The hypertrophy of the heart is predominately a lesion of the left ventricle. In the majority of cases the left ventricle alone is affected; in the remainder of cases both ventricles are involved; the right ventricle is never implicated alone. Simple hypertrophy of the left ventricle is the first event; later this may be associated with some dilation—eccentric hypertrophy. The longer the nephritis continues (the longer the patient lives) the more certain the development of consecutive enlargement of the right ventricle—the increased pressure in the left ventricle gradually leading to the same condition in the right ventricle. Here the hypertrophy is also of the eccentric variety. Predominating dilation of either or both ventricles is an unusual event until toward the termination of the disease; its development is of ominous moment—it usually presages a fatal termination. It has been claimed by Senator and others that the hypertrophy of the primarily contracted kidney or renal cirrhosis is of the simple variety, whereas that associated with the secondarily contracted

* Read by title at a meeting of the Medical Society of the State of Pennsylvania, held at Wilkesbarre, September 18, 19, and 20, 1900.

kidney or chronic parenchymatous nephritis and with the arteriosclerotic kidney is of the eccentric variety—hypertrophy with dilation.

This hypertrophy of the heart is found in association with all forms of nephritis, but not with all cases. In none of the varieties, however, does it so dominate the clinical picture as it does in the primarily contracted kidney or chronic interstitial nephritis. It may be expected from the time of the contraction or atrophy of the kidney, be it of the primary or secondary variety. Thus it arises early in the primary form, but its occurrence may be much delayed in the secondary variety. It may, however, occur in chronic parenchymatous nephritis without contraction or atrophy, and it has been noted also in acute nephritis in a considerable proportion of the cases—particularly in the acute nephritis following infections, such as scarlet and typhoid fevers, etc. In some of the chronic cases in which it would naturally be expected, for some more or less inexplicable reason it is missed. These cases, however, are of relative infrequency. The absence of the hypertrophy may be due to faulty nutrition—the heart being insufficiently well nourished to enable it to hypertrophy; to arteriosclerosis of the coronary vessels; to the vicarious action of one of the excretories removing those excrementitious products ordinarily eliminated by the healthy kidney; and to the fact that minor grades of hypertrophy are sometimes overlooked at necropsy, although during life there were present sufficient clinical evidence to warrant their diagnosis.

Of the signs of the cardiac disease in chronic nephritis that which will immediately arrest the attention of the observant clinician is displacement of the apex beat. This is one of the most valuable signs of hypertrophy of the left ventricle, as it is of disease of the heart in general. Such is its importance that it may with truth be asserted that in the great majority of cases that heart is not seriously disordered whose apex beat is in the normal situation. The displacement of the apex beat characteristic of hypertrophy of the left ventricle is downward and outward. It may be found in the sixth, seventh, or eighth interspace outside of the nipple line, even as far as the midaxillary line. In addition, unless there be much dilation or degeneration of the heart, the apex beat is heaving in character, and fairly well circumscribed, though it is broader than is normal. However, it does not approach in width that found in hypertrophy of the right ventricle. This dislocation of the apex beat may be encountered early in the course of the disease; and it usually proceeds further downward and outward as the disease of the kidney progresses.

Further evidence of hypertrophy of the left ventricle—as also of increased tension in the arterial system—is found in the marked accentuation of the aortic second sound of the heart. This is the second of the cardiovascular manifestations of chronic nephritis, but it is hardly secondary in importance to that of the other physical signs of hypertrophy of the left ventricle. Indeed, in many instances it can be clearly appreciated when enlargement of the cardiac dulness and displacement of the apex beat are at most problematic. Such is its importance that, in the absence of other causes to account for it, it is extremely suggestive of chronic nephritis. The latter is even its most common cause. When heard it should always awaken the suspicion of nephritis, and even in the absence of albumin in the urine the probability of such kidney disease must not

be abandoned until the accentuation of the second sound be otherwise adequately accounted for, and until long-continued and patient observation determine the nonexistence of nephritis. It is often the first indication of the insidiously developing chronic nephritis, and may be heard in many instances before enlargement of the heart or increased tension of the radial pulse can be determined.

The latter, increased tension, which may be appreciated in the radial as well as in other arteries, is one of the most valuable signs of chronic interstitial nephritis. It may be expected from the commencement of the disease. The pulse of high tension is quite characteristic—it is hard and resistant to the palpating finger, it remains persistently full even between beats, and it requires considerable pressure with the fingers to completely arrest the pulsations. The sphygmographic tracings are also quite distinctive. This increased tension of the pulse is, of course, found in some other conditions, and in establishing a differential diagnosis, these, of course, must be eliminated. The conditions with which it is most frequently found associated are often themselves the cause of chronic nephritis, such as lead, gout, arteriosclerosis, etc. Thus the sign is of value as indicating the operation of a cause which may lead to chronic nephritis if it has not already done so. It is also found in connection with plethora, contraction of the arterioles, as by a chill, some cases of hysteria, diabetes, mitral stenosis, etc.; but these conditions are readily discriminated. Of such importance and significance and so distinctive is this increased tension that some clinicians have asserted their ability to recognize cirrhosis of the kidney from it alone.

The existence of these cardiovascular alterations, as also the kidney changes, may for a long time remain entirely unknown to the patient and be entirely unsuspected by the physician. Whatever be the exact cause of their production (and many theories have been advanced, but as yet the correctness of none has been conclusively demonstrated), it is certain that they arise in response to excessive demands on the part of the general economy. So long as the heart continues to perform its augmented work well no symptoms arise. Inquiry, however, in some cases will elicit the information that for years possibly, excitement and exertion have been provocative of breathlessness and palpitation of the heart; but having an obvious cause they were regarded as insignificant. As the disease advances, however, the nutrition of the heart no longer keeps pace with its enlargement, degenerations ensue, and evidences of embarrassed circulation result. It is now that symptoms referable to the cardiovascular system dominate the clinical picture. To the hypertrophy of the heart, if it have been simple, there supervenes dilation, and to disease of the left ventricle are added similar alterations of the right. There result cardiac asthma, congestion and edema of the lungs, bronchitis, gastrointestinal disturbances, diminution in the daily quantity of urine secreted, and generalized edema. The symptoms referable to the heart and lungs at first transitory and nocturnal become permanent, the other symptoms narrated are added, and if relief be not afforded, death ensues with cardiac failure or uremia dominating the final scene. Toward the end, the pulse which had been of high tension, loses somewhat in this particular, the second aortic sound becomes less accentuated, the second pulmonary sound becomes accentuated with embarrassment of the right heart, the

signs of dilation are manifest, and galop rhythm' always of serious moment, supervenes.

From a diagnostic point of view the importance of the cardiovascular alterations in chronic nephritis cannot be overestimated. They are among the earliest clinical manifestations of the disease, and they may be detected even in the absence of positive indications on the part of the urine. Such is their double import, that in the event of the suspicion of chronic nephritis they should be diligently sought for, and in the event of their accidental detection in the course of the routine examination of a patient, the presence of an unsuspected or latent renal cirrhosis must be persistently borne in mind until these signs be otherwise adequately accounted for. These cardiovascular alterations may be expected in all cases of chronic interstitial nephritis; in a few cases, as already intimated, they will not be found. From the very nature of the disease, one of its first consequences is augmentation of the arterial pressure. This, while it may possibly exist for a short time unaccompanied by alterations in the heart-muscle, if long continued is speedily followed by hypertrophy of the left ventricle. This, then, it may well be urged, is a part of the disease. Chronic interstitial nephritis then is not merely a local disease affecting the kidneys only; it is in many instances a widespread disease affecting in addition the entire vascular apparatus,—the heart and arteries especially, but sometimes also the veins. This is well appreciated by the separate recognition of a special form of nephritis—the arteriosclerotic form of contracted kidney. But is not also the ordinary form of renal cirrhosis a widespread disease? In the majority of cases the disease doubtless commences in the kidneys but it speedily implicates other structures; sometimes even analogous lesions have been found in organs as remote as the liver, etc. In some cases, however, it is extremely likely that the lesions commence simultaneously in the kidneys and the cardiovascular apparatus.

In the stage of cardiac compensation, the diagnosis of renal cirrhosis is sufficiently evident from an inquiry into the antecedents of the patient, the special etiologic factors in the case, the course of the disease, the various clinical manifestations, and an examination of the urine and the cardiovascular apparatus. Indeed a diagnosis based upon increased tension of the pulse, accentuation of the aortic second sound of the heart, and the other physical signs of hypertrophy of the left ventricle, will rarely be wrong.

It is, however, when lack of cardiac compensation occurs that diagnostic difficulties may arise. The clinical picture in these cases much resembles that of an affection primarily cardiac and secondarily renal. Given a patient with evident lack of cardiac compensation; with signs of hypertrophy and dilation of the heart, but with such dilation that it may be well nigh impossible to determine accurately which side of the organ is especially involved; with or without murmurs; with albumin and casts in his urine—does he suffer with a condition primarily cardiac and secondarily renal, or vice versa? is the affection one of a primary heart lesion with secondary congestion or cyanotic induration of the kidney, or is it one of a primary kidney lesion with secondary hypertrophy and dilation of the heart? The question is extremely difficult to settle off hand. But be it the one or the other, the close interrelationship between the heart and kidney in disease is well illustrated. In either case the general condition

of the patient is much the same; there are the general and local evidences of embarrassed circulation, and the urine is diminished in quantity, increased in coloring matter and specific gravity, and contains albumin and casts. The presence or absence of murmurs is not definitely diagnostic unless it be possible to accurately localize them and refer them to positive valvular defects. We will remember that if there be marked cardiac debility, a murmur of some valvular defect may be temporarily absent; on the other hand, in renal cirrhosis, if the cardiac dilation be sufficient there may arise a relative mitral incompetency, and a murmur not heard previously becomes audible. Thus murmurs complicate the situation. In the majority of cases, however, the diagnosis can be made by bearing in mind that in congestion of the kidney, the casts are usually hyalin only, and that the quantity of albumin, which may be considerable, varies from time to time with the state of the cardiac activity—it increases or decreases in amount with impairment or improvement in the condition of the heart. Again, in renal congestion we endeavor to ascertain the cause, by reference to the past history of the patient, and by noting that the kidney lesion is but part of a general condition which finds its expression also in congestion of the liver and spleen, effusions within the several serous cavities, anasarca, etc. If, however, the urine remains albuminous despite the subsidence of signs of congestion in other portions of the body, if the specific gravity of the urine lessens, and if in addition to hyalin, even a few epithelial casts are discovered, maybe also some erythrocytes, it is evident that in addition to the congestion of the kidney there exists a nephritis. Whether or not this is a condition long standing or the final result of long-continued congestion remains to be decided by reference to the past history of the patient. It is in these cases that the therapeutic test is of the greatest diagnostic utility. It is in these cases that digitalis is urgently indicated. If, as sometimes happens, the exhibition of the digitalis is followed by marked improvement in the condition of the patient, with final absence of casts and albumin from the urine, the condition is definitely determined to be one of renal congestion. If, however, with improvement in the cardiac condition, albumin and casts do not disappear from the urine, we are then confident of the existence of nephritis, and this opinion will be further confirmed by the examination of the cardiovascular apparatus, now that compensation has been more or less restored.

Not only does the condition of the cardiovascular apparatus dominate the diagnosis of chronic interstitial nephritis, but it likewise assumes a commanding position in the prognosis and therapeutics. In the very early stages of the condition, in the stage when the condition is accidentally discovered before there are any clinical evidences of its existence, the prognosis is not bad with regard to life-expectancy. The patient, however, should be warned of his affliction and advised to lead a hygienic, moral, and abstemious life. In the later stages the factors that most influence prognosis are the condition of the cardiovascular system, the quantity of urine excreted daily, the manifestations of uremia, and the presence or absence of secondary inflammations, particularly of the serous membranes. With embarrassment of the circulation, the prognosis becomes very bad. Compensation when it once fails, is sometimes never recovered; with judicious treatment, however, the patient may be tided over the critical

period and live, if careful, for a number of years. It is especially important to watch the quantity of urine excreted daily. Diminution in the quantity of urine often presages the onset of uremia, which, however, may be averted by timely interference. The importance of the condition of the heart is here again brought into evidence, as failure of the cardiac power has as a consequence diminution of the quantity of urine. This lessening of the quantity of urine is especially a cause for concern if associated with headache, and both demand immediate attention.

In referring especially to the treatment of the disease it is to that stage of the affection when it is generally recognized that I wish to allude,—to the stage of cardiac hypertrophy. It is here again that the cardiovascular alterations dominate the situation. The dangers most to be apprehended are cardiac failure, rupture of the smaller arteries, especially those of the brain, and the development of uremia. The first two depend entirely upon the condition of the heart and bloodvessels; the last named in part only. When the patient presents himself complaining of the passage of large quantities of urine and of dyspnea on exertion, the nature of the affection should be recognized after careful examination of the urine and the heart and bloodvessels. It is now, appreciating our inability to definitely cure the patient, that we must be alert to the dangers that threaten him. He must be cautioned not to expose himself to the inclemencies of the weather, he must avoid all excessive muscular exercise, and if possible, all mental worry; he must keep his bowels regular and in every way favor the action of the skin, so that as little work as possible may be thrown upon his diseased kidneys, heart and bloodvessels. The skin, though a poor substitute for the kidneys, is still capable of performing considerable excretory work, and its action should be facilitated as much as possible,—by wearing underclothing suitable, and by a daily tepid bath. Hot baths may be given, but not indiscriminately; they are contraindicated if they increase blood-pressure to such an extent as to cause unpleasant throbbings. The diet is of the utmost importance, and probably the duration of life depends as much upon discretion in eating and drinking as upon any other factor. It is advisable in many cases to try a more or less exclusive milk diet for a while. If the patient be obliged to take to bed, this is all the more indicated. After a while fruits and vegetables should be added, and at all times large quantities of pure wholesome water should be taken. Whether or not albuminous food be allowed must be decided in the individual case. In some cases it will be well to withhold it entirely for a time at least; in others moderate quantities may be permitted with good effect. Large quantities are certainly injurious. And it is equally certain that in many cases the exclusion of proteids from the dietary is not followed by good results. A wise rule is to permit some of the lean and easily digested meats to be partaken of once a day. Eggs are also very suitable, and will be found of exceeding service when taken raw. Tea and coffee in moderation are permissible; alcoholic beverages, however, should be strictly prohibited. In many cases, the above with an occasional saline purge for its depletive effect and its tendency to lower blood-pressure, will suffice to produce amelioration of all symptoms. If such be the case, no medicines should be given. There will come a time when they will be required, and that the best results be obtained they should be withheld until required.

When, however, the heart begins to flag, to be no longer equal to the demands, medication is called for, and under these circumstances I know of no better remedies than nitroglycerin and caffeine. It so happens that the patients that I have seen of recent years have done better when given both remedies in conjunction, than they have on nitroglycerin alone. The nitroglycerin may be given in tablets of $\frac{1}{100}$ grain each, or in one minim doses of the 1% solution, three or four times a day. This dose may be gradually increased until the desired results be obtained. The caffeine is best given in three-grain doses at the same time. More than three grains will rarely be indicated. Nitroglycerin not only lowers the high arterial tension, but at the same time it favors the reduction in the amount of albumin excreted, and permits the heart, still in itself capable of performing its work, to do so, unhindered by the excessive pressure against which it formerly worked. It is not necessary to give nitroglycerin to the extent of producing unpleasant symptoms; sufficient reduction of the arterial tension is usually produced before this. We have to bear in mind that it is not advisable to reduce the pressure to that of the normal individual. A certain amount of increased tension is desirable in renal cirrhosis; for unless there be increased tension, the quantity of urine excreted falls, the uremia is a likely event. I believe also that the gentle stimulus to the heart produced by the caffeine, as well as its diuretic action on the kidneys, tend for good in this disease. Certain it is that really remarkable benefit follows the administration of these remedies in many cases. But each case must be studied individually. In some instances the dose of nitroglycerin must be greatly above that I have mentioned to produce the desirable effect. But the proper dosage being obtained, marked amelioration and complete cessation of the dyspnea, vertigo, headache, compression in the head, etc., frequently follow. Even in advanced cases, when dyspnea is so pronounced as to prevent sleep, I have seen several days of this medication productive of such relief that refreshing sleep was obtained. It is well to continue this treatment for four to six weeks, and then to interrupt it for a week or ten days, if the patient's condition does not demand a return sooner. The nitrite of sodium or potassium may be substituted for the nitroglycerin, as its action is similar. I have had less experience with these, but I believe them hardly as efficacious as nitroglycerin. It is well to remember that the nitrites interfere somewhat with the oxygenating power of the blood, and for this reason, if no other, their continuous administration should not be persisted in too long.

This treatment by nitroglycerin and caffeine will also be found efficacious in warding off an attack of uremia that shows its imminence in headache, restlessness, foul breath, coated tongue, vertigo, diarrhea, etc. In this condition it is well to restrict the diet to milk, and to give large quantities of water, as well as to add saline cathartics, and alkaline diuretics. The treatment of the more severe attacks of uremia hardly enters within the scope of this communication.

When there is no marked cardiac debility there are several drugs that I believe should not be given. Of these digitalis should be mentioned first. The routine habit of administering digitalis whenever there arises indications of some interference with the heart's action is much to be deprecated. Digitalis in this stage of the disease does more harm than good, and should be withheld. The routine administration of iron because a

patient has nephritis is also not to be commended. In this form of nephritis there is, as a rule, little anemia, and iron is not called for; on the other hand, it is contraindicated on account of its astringent action, its tendency to constipate, and it doubtless also tends to augment the headache. In the late stages of parenchymatous nephritis it is a good remedy, but I believe it is not so useful in renal cirrhosis. When anemia develops, as it does sometimes late, it may be given with hope of good results.

When marked cardiac dilation arises and there occur the signs of lack of compensation, the time has arrived for the administration of digitalis. This should be given in large doses, and if good results be not obtained within four days, it should be discontinued, as it is likely not to prove of utility. Strophanthus should be substituted. After several days of intermission, if the symptoms continue urgent, digitalis may be tried again, and will often be followed by the desired results. Even if it prove efficacious in the first instance, it is well to discontinue its administration after 10 days or thereabouts. After the lapse of a similar period if indicated it may be given again. Strychnin also is a most efficacious remedy and may be given with expectation of happy results in any stage of the disease. It is of value not alone for its general tonic effect, but it proves especially useful to that heart that shows the slightest embarrassment. It may be given for long periods and either alone or in conjunction with other remedies. It is extremely useful in the acute dilations of the heart when the symptoms are always urgent. Under these circumstances it may be given hypodermically. Hypodermics of camphor in olive oil are also useful in this condition.

There are several other remedies, such as the iodids and mercuric chlorid, for which great virtues have been claimed in the treatment of renal cirrhosis. It is even asserted that low specific gravity of the urine and high arterial tension are direct indications for the administration of the iodids. I believe, however, with many others, that little good follows their use in the advanced stages of the disease; in the early stages, particularly if there be considerable arteriosclerosis, their use may be attended by much good. It is even possible that their exhibition over long periods may operate to retard the progress of the disease. There are many other details of the treatment of renal cirrhosis including the various manifestations of uremia, that are as interesting as they are important. But lack of time and space forbid their consideration.

A CASE OF PROGRESSIVE PERNICIOUS ANEMIA.

By L. M. VAN METER, M.D.,

of Philadelphia, Pa.

Resident Physician to the Pennsylvania Hospital.

THE following case of progressive pernicious anemia, occurring in the service of Dr. Arthur V. Meigs at the Pennsylvania Hospital, is interesting because of the high grade of anemia which it presents.

John F., white, of German birth, married, by occupation a wagon-driver, was admitted to the hospital March 5, 1900, with the following history:

Family history, negative. His previous health had generally been good, the only illness which he recalls being measles at 9 years of age, and, one year ago, an attack similar to the present, accompanied by weakness, fatigue, breathlessness

upon slight exertion, and, as he terms it, a yellow color of the skin. He suffered no pain and noticed no edema. He was not prostrated by this attack; but continued at light work, and gradually returned to something like his normal condition. He had never been addicted to the use of alcohol, and denied venereal infection. Eight weeks before admission he began to feel tired and easily exhausted. He had been exposed in his occupation of driver, and felt as though he had taken cold. He had no pain nor especial distress, and the pulmonary symptoms were slight; but he grew steadily weaker and wasted in flesh. His skin, he asserts, turned "yellow." Two weeks before coming to the hospital his feet and legs became edematous. The flow of urine increased, so that he arose three or four times during the night. His appetite was poor and his bowels loose; sleep was sound, but not refreshing. Hearing and vision seemed unimpaired.

Physical examination showed the patient to be a man of large frame and good muscular development, with a moderate degree of emaciation, and slight puffiness of the lids and face. The skin was dry, scaly, exceedingly pale, and of a light lemon tint, with superficial areas of brownish pigmentation distributed here and there over the body. The hair was dry and brittle; tongue, lips, and conjunctiva blanched and bloodless; sclera of pearly whiteness. His teeth were in an extremely bad condition, 10 of the molars and premolars being in an advanced stage of carionecrosis, and all of the rest being dark, soft, and more or less necrotic. This fact is interesting in connection with the recent investigations of William Hunter.¹

There was nowhere any enlargement of the lymphatic glands. The pulse was small, quick, and compressible; vessels soft and elastic. Examination of the heart revealed the apex-beat in the fourth interspace, about one inch internal to the left mammillary line. The impulse imparted to the touch was feeble, quick, and jerky. Upon auscultation, the action was rapid, and the sounds booming. There was a soft, systolic murmur heard over the left base, less distinctly at the apex, and in the great vessels of the neck. Slight epigastric pulsation was also noted. The chest was full and well developed. Physical examination of the lungs was negative save for impairment of resonance over the bases with feeble breath-sounds and a few crepitant rales. The liver-dulness began at the sixth rib in the parasternal line and extended two inches below the costal border, where it offered resistance to palpation, though the border could not be distinctly defined. The abdomen was concave and otherwise negative.

Examination of the urine showed: color, amber; reaction, acid; specific gravity, 1.012; no albumin nor sugar. Microscopically, the sediment was negative.

The blood-examination, three days after admission, by Dr. J. Alison Scott was as follows:

Red cells	880,000 per c.mm.
White cells	3,000 " "
Hemoglobin	15%

Megalocytes existed in profusion and a marked poikilocytosis, some cells being polychromatic. A differential count was not made at this time.

A second blood-examination made 19 days after admission showed:

Red cells	390,000 per c.mm.
White cells	2,000 " "
Hemoglobin	14%

and a differential count:

Polynuclear neutrophiles	31%
Small lymphocytes	53%
Large and transitional	11%
Eosinophiles	4%
Myelocytes	1%

Four normoblasts and 15 megaloblasts were seen in counting 200 whites.

A third count made 26 days after admission revealed:

Red cells	896,000 per c.mm.
White cells	4,000 " "
Hemoglobin	33%

Differential count:

Polynuclear neutrophiles	52%
Small lymphocytes	36%
Large lymphocytes	4.7%
Eosinophiles	3%
Myelocytes	4%

¹ *Lancet*, January 27, February 3 and 10, 1900.

There were 17 normoblasts and 13 megaloblasts per 1,000. There has been a slight elevation of temperature since admission, varying between 97° and 102.6°.

The patient's condition has been comfortable, except for an otitis media of the left ear of slight severity, accompanied by moderate pain, and a slightly higher temperature-range. He has been kept in bed upon simple, nourishing diet, and given iron and arsenic. Upon this regimen he has shown a marked improvement. An ophthalmoscopic examination has recently been made, showing in one retina a small striated hemorrhage, and in the other, a larger one of similar character, each located some distance to the temporal side of the optic disk. The lemon tint has disappeared from the skin, and the lips are becoming pink. There has been no hemoglobinuria.

THE SIGNIFICANCE OF DIACETIC ACID IN THE URINE.¹

By C. K. JOHNSON, M.D.,
of Burlington, Vt.

DIACETIC or ethyl-diacetic acid (C-6, H-10, O-3,) is a colorless, strongly acid liquid. On heating to boiling, it decomposes into carbondioxid and acetone, hence the necessity of making tests previous to boiling the urine. It gives a dark red color with a solution of ferric chlorid. There are certain other substances which may give the ferric chlorid reaction. The urine of patients who have taken salicylic acid, carbolic acid, or antipyrin may give the reaction. The red color, however, from the presence of diacetic acid, disappears upon boiling, or is not produced if the urine be previously boiled, while that due to the other substances is unchanged by boiling.

Diaceturia is always pathologic and may usually be regarded as a serious symptom. It is of least serious significance when occurring, as is not uncommon, in acute febrile conditions in children. In these cases recovery usually follows. In adults it is a more serious symptom. Purdy states that in diabetes mellitus the occurrence of diaceturia may be looked upon as a very probable prelude to coma, which usually terminates quickly in death. Some writers claim that diabetic coma is due to the presence of diacetic acid in the blood, and propose to call it diacetic coma. Diaceturia is sometimes accompanied by such symptoms as vomiting, dyspnea, and restlessness, which may shortly end in death without other discoverable lesion.

Detection may be accomplished as follows: first, take a recently voided sample of urine and add a few drops of ferric-chlorid solution to it. If the phosphates are precipitated filter them off, and to the filtrate add a few more drops of the ferric-chlorid solution. If a dark red color is produced diacetic acid is probably present. Second, the above color disappears on boiling or is not produced if the urine be previously boiled. Third, acidify the urine with sulphuric acid and shake with ether, next shake the removed ether with very dilute ferric chlorid, and the water color becomes claret-red.

The exact relation between diacetic acid and acetone is not perfectly understood. Acetone, however, may be found in the urine under normal conditions, and is

greatly influenced by the character of the diet. Whenever the carbohydrates are withdrawn the quantity is rapidly increased and reaches its maximum in 6 or 7 days. If carbohydrates are again added to the diet the acetone soon diminishes. This result does not follow if fats are substituted for the carbohydrates.

Some writers state that the amount of acetone stands in direct relation to the intensity of the disease, increasing towards the fatal end. This, however, is still an open question.

The threatening symptoms already alluded to, viz., vomiting, restlessness, and dyspnea, with tendency to coma, will often disappear when carbohydrates are administered in large amounts. Diabetic coma is more apt to occur when the old-fashioned plan of excluding carbohydrates entirely is adopted.

A very simple explanation of this would be as follows: As previously stated, diacetic acid on heating breaks up into acetone and carbon dioxid; following this theory the excess of acetone in diabetic urine would unite with the free CO₂ normally found in urine to form diacetic acid; hence, when carbohydrates are added to the diet causing a reduction of acetone, the formation of diacetic acid is prevented.

Acetone may be detected by the following method: To a recently voided sample of urine add Lugol's solution carefully until a brown color is produced; then add liquor sodae, until the urine becomes clear, when iodoform will be precipitated as a yellow powder, a distinct odor of iodoform will also be produced if acetone be present.

The following is a report of a case of diabetes in a girl 12 years old. The first symptom of an abnormal condition was frequent micturition, especially during the night. A physician was first consulted February 9, 1900. At this time she was somewhat restless and often complained of headache. She was passing about four quarts of urine in 24 hours. An examination showed a high specific gravity with a large amount of sugar. No quantitative analysis was made. The case first came to my notice March 4. The child then showed marked restlessness, but was fairly well nourished. Upon examination of the urine I found a specific gravity of 1.038, sugar 4%, urea 7 grains to the ounce. Both diacetic acid and acetone were present. Microscopic examination showed a few granular casts, few squamous and renal cells, and a few leukocytes. The child continued to grow more restless, not being inclined to play until March 16, when she was taken with vomiting. This continued at intervals until the following day, when she felt somewhat relieved. On March 18 she became comatose and remained in this condition until 10 o'clock on March 19, when she died.

The point which I consider this case to illustrate is simply this: that the presence of diacetic acid in the urine of a diabetic patient is a grave symptom and may usually be looked upon as a very probable prelude to coma, which usually terminates quickly in death.

Famine in India.—The Viceroy of India, in a speech before the Council at Simla, recently said the famine had affected a quarter of the population of India, and that even now two millions of people were receiving relief. He expressed the hope, however, that in a month these would return to their homes. He said that half a million deaths were traceable to the famine, and that the failure of the crops involved the loss of fifty millions sterling, plus some millions for loss of cattle.

Patriotism and the Zeitgeist in Medicine.—We congratulate our readers upon the presentation of the newer methods of anesthesia set forth in the noteworthy contributions of the foregoing issue. But there is one too mortifying conclusion: Medical attention and practice is sadly subject to waves of popular opinion. The work of Corning led to few or no practical results with American surgeons, until the method was taken up by European operators. Then and not till then did it strike our attention! But if it was valuable when recommended by Tuffier, then it was valuable when recommended by Corning. Worse than the neglect is the fact that the American originator of the method was not only forgotten, but the credit was ascribed by one of the most enlightened representatives of the medical press in New York, to Professor Bier, of Kiel. It is, however, gratifying that one great American surgeon had recognized its possibilities of usefulness before the Zeitgeist fire had been set ablaze. As early as November 10, 1899, Matas had successfully employed it, and as early as June 3, 1899, he had publicly called attention to the American origin of the method. But again no attention was paid to this, and American operators still refused to light the flame of their practical enthusiasm at any except the European lamp. A second cause for congratulation, however, lies in the further history, whence it appears that with eminent sanity Matas rated the method with a sound conservative judgment, before the American traveler had returned from Paris in the summer of 1900. In view of this fact we wonder if Matas' commendation of the methods of local and regional anesthesia must await a European mirror to attract our patriotic attention.

A statistical contribution of exceptional value, as regards the history of anesthetics, and especially concerning the use of ether in the Zurich clinic, has been compiled by Dr. Johanna Gunning. We epitomize from the *Beiträge zur klinischen Chirurgie* (Band 28, No. 1) the results since 1894 of a very careful surgeon, concerning the effects of the administration of ether alone, and of ether combined with morphin. Before 1894, Prof. Krönlein had used for 13 years chloroform almost exclusively, but, led by the demonstrations of its bad effects on the heart, he has changed to ether as his usual anesthetic. From 1894 to 1899 he had some 2,068 cases of narcosis with adults and 4 cases

with children under 6 years. The routine method of preparation was to give the patient only a cup of milk or soup the evening before in order to have an empty stomach for the morning operation. He uses the Juliard mask, in size 20 cm. long, 15 cm. wide, and 12 cm. high, with the Roser-König or Heister gag, and the Krönlein tongue-holder. For face-operations he has also the little bromethyl mask. The ether is purchased in colored bottles containing 100 ccm. each, 10 to 20 ccm. are poured into the mask, which is at first held not very close to the face and the patient allowed to get used to the fumes and told to breathe naturally. After a couple of minutes 10 to 20 ccm. more are poured into the mask. In this way it is necessary to bind only the patient's legs. The narcosis is complete after an average of 4 minutes—even before the corneal reflex has disappeared. An effort is made to keep the amount of ether used as small as possible, with the result that Zurich uses about $\frac{1}{2}$ as much per minute as the usual statistics report as necessary. The ether is given alone and in combination with an injection of 0.01 to 0.015 morphin $\frac{1}{2}$ hour before the operation. This has been found specially good for the treatment of alcoholics and for cases in which an incomplete narcosis is used, as in resections of the jaw or in strumectomies. But in October, 1897, the clinic had a death after the use of morphin, in which morphin poisoning seemed to have played a role, and since then Prof. Krönlein has used the morphin as little as possible. The contraindications to the use of ether are: in young children (therefore the few cases reported), bronchitis, and emphysema (in the last two cases use local anesthesia if possible). Ether is therefore more usable than chloroform, which latter has injurious effects not only on the heart but also on the liver and kidneys. The record follows: 6 cases of use with children under 6 years, average amount of ether used 91.2 ccm., and per minute 1.6 ccm.

There were 31 operations for head, face and neck in which ether alone was used 9 times (average amount 143.3 ccm., and per minute 2.1 ccm.) and morphin with ether 22 times (average amount of ether 154 ccm. and 1.9 per minute). These were all half or incomplete narcoses in order to avoid the aspiration of blood, etc. Prof. Krönlein thus avoids the necessity for tracheotomy, etc. Twenty-seven of these narcoses were quiet, 1 case developed a heart-disturbance, 1 case bilious vomiting, and 2 cases had an excitement stage. There were 2

deaths among those operated, from pneumonia, in which one can believe that the ether had a bad influence.

There were 206 cases of strumectomy: with ether alone, 129 times, and with morphin 77 times (0.015 to 0.017); 184 of these passed without incident and 2 had heart disturbance, 6 vomiting, and 13 excitement stage, and 1 with tremor. In one death after operation the influence of the anesthetic could be seen. It must be noted here that Prof. Krönlein does not operate for goiter from cosmetic reasons alone, and that therefore most of these cases had some difficulty with the respiratory organs beforehand.

There were 55 cases of mamma extirpation: ether alone 52 (average amount 116 ccm., and per minute 2.6 ccm.); with morphin 3 times (average amount 140, per minute 4 ccm.); 50 cases were quiet, 1 had tracheitis, 1 vomiting, 2 excitement stage, 2 tremor.

There were 298 laparotomies, with ether alone 255 cases (average amount 154.7 ccm., per minute 2.4 ccm.); with morphin, 43 cases (average amount 163.6 ccm., per minute 2.3 ccm.). Of these, 273 cases were quiet, 1 had heart-disturbance, 13 vomiting, 7 excitement (2 alcoholics), 1 tremor. There was 1 death 5 days after operation, and 5 cases of slow waking.

There were 279 cases of herniotomy, with ether alone 263 (average amount 109.6 ccm., per minute 2.2 ccm.); with morphin, 16 (average amount 181.2 ccm., per minute 3.4 ccm.). Of these, 224 were quiet, 2 showed tracheitis, 1 coughing, 1 weak pulse, 14 vomiting, 32 excitement (4 alcoholics), 4 tremor. There was 1 case of vomiting after the narcosis.

There were 13 cases of nephrectomy, with ether alone 12 times (average amount 135.4 ccm., and per minute 1.9 ccm.); with morphin 1 (320 ccm., or 3.5 ccm. per minute). Eleven cases were quiet, 1 was cyanotic, 1 had weak pulse, 1 with collapse *after* operation.

There were 30 cases of urethrotomy, with ether alone 28 times (average amount 153 ccm. and 3.6 ccm. per minute); with morphin 2 (average amount 175 ccm., and 2.9 ccm. per minute). Of these, 29 cases were quiet, 4 excited, 2 showed vomiting.

There were 269 extirpations of tumors, with ether alone 241 times (average amount 169 ccm., per minute 2.2 ccm.); with morphin (0.015) 28 times (average amount 149.4 cc., and per minute .4 ccm.). In 227 of these cases narcosis passed off quietly, 2 had bad pulse, 1 dilation of pupils, 13 vomiting, 25 excited stage (5 alcoholics), and 1 tremor. There was 1 case of slow waking.

There were 163 cases of amputations, exarticulations and resections; ether alone was used 155 times (average amount 122.1 ccm., and per minute 2.7 ccm.); with morphin (0.015) 8 times (average amount 140.6 ccm. and per minute 2.2 ccm.). Of these, 126 cases were quiet, 3 had bad respiration, 3 bad pulse, 11 vomiting (2 alcoholics), 5 tremor, 2 rigidity of muscles. After the operation 1 vomited and 1 waked slowly.

There were 25 cases of osteotomy, all with ether alone (average amount 104 ccm., and per minute 3 ccm.); 20 cases were quiet, 3 vomited and 2 had excited stage.

There were 5 cases of myotomy, all with ether alone (average amount 45 ccm., and per minute 2 ccm.); 3 were quiet and 2 had excited stage.

There were 10 cases of neurectomy, tendons and nerve knot, with ether alone 9 times (average amount 141.6 ccm., and per minute 2.7 ccm.); with morphin (0.015) 1 case (190 ccm., and 2.5 ccm. per minute); 8 were quiet and 2 excited (1 was an alcoholic).

There were 18 cases of cauterization, all with ether alone (average amount 109.7 ccm., and 4 ccm. per minute); 15 were quiet, 1 cyanotic, 2 excited.

There were 549 cases of incision and empyema operation, with ether alone 546 times (average amount 82.8 ccm., and per minute 3.2 ccm.); with morphin 3 (0.015) times (average amount 166.6 ccm., and 2.1 ccm. per minute); 477 cases were quiet, 5 had respiratory disturbance, 4 had heart, 10 vomiting, 50 excited stage (3 alcoholics), 1 rigid muscles, 1 tremor, 1 chronic twitching. After the operation 2 vomited and 1 waked slowly.

There were 47 cases of reposition of joints, etc., all with ether alone (average amount 75 ccm., and per minute 3.5 ccm.); 36 cases were quiet, 1 had respiratory disturbance, 7 excited stage (1 alcoholic), and 1 vomited.

There were 52 patients anesthetized for examination, and removal of foreign bodies, all with ether alone (average amount 57.7 ccm., and 3 ccm. per minute); 49 were quiet and 3 excited.

There were 12 cases of skin-transplantation, all with ether alone (average amount 103.7 ccm., and 2.8 ccm. per minute). All were quiet.

There were 6 cases of ligature of arteries, all with ether alone (average amount 206 ccm., and 6.1 ccm. per minute). All were quiet.

In general, morphin was given when the operation was expected to be long, and the opinion of the physicians in charge is that its use decreased materially the amount of ether used. Prof. Krönlein believes that he has had less vomiting with ether than he used to have with chloroform.

Viability of the Plague Bacillus in Sputum.—As is well known, pulmonary complications in plague are not uncommon. In addition to the pneumonic type of the disease, there are frequent instances of bronchopneumonia occurring in cases of ordinary bubonic plague. In both of these forms of the disease it has been found that the plague bacillus occurs in the sputum, and that, during the activity of the lung disorder, the microbe displays great virulence. How long after the recovery of the patient this virulence of the bacillus in the sputum continues, has been debated. This is obviously a most important question, since the propagation of plague by this means would very readily occur. According to the observations of Gotschlich, at Alexandria, virulent

plague bacilli may be found in the sputa of convalescents from pneumonic plague, not only during the disease itself, but even 20, 33, and 48 days after complete defervescence. In order to test this important question, Dr. Métin, of the French colonial medical service, undertook a series of experiments during the recent epidemic of plague at Oporto. His paper has been translated by Dr. H. D. Geddings, and published in the *Health Reports* of the United States Marine-Hospital Service. The method of Métin was by inoculation of guineapigs in the peritoneal cavity with the sputa of convalescents from plague. The sputa of these patients during the height of the disease caused the death of the animals in from 3 to 5 days, and the specific *coccobacillus* was recovered in pure culture in the organs after death. The results of a series of experiments were quite uniform. First, a guineapig was inoculated with sputum during the height of the disease. The sputum at this time usually showed numerous plague bacilli. As a uniform result, the pig thus inoculated died in a few days. After convalescence was established, the sputum from the patient was again used at various intervals of time, and the results noted. As a rule, the virulence of the sputum was maintained during the first week, or a little longer, and then seemed rapidly to decrease. Thus in one case, a guineapig, inoculated 7 days after defervescence, developed buboes and died in a few days. Another pig, inoculated from the same patient, on the fourteenth day, did not sicken at all. The patients used for these experiments were 8 in number. Two had had primary pneumonic plague, and 6 had had ordinary bubonic plague with bronchopneumonia.

The conclusions drawn by Métin are that the virulence of the sputum diminishes even by the end of the first week; for, although fatal at this time to guineapigs, it does not kill them in so short a time as the sputum taken during the fastigium. After the ninth day, the sputum seems to have lost its virulence completely. During the 8 or 9 days in which the sputum is fatal to guineapigs, Métin was never able to find in it the plague bacilli by microscopic examinations of direct preparations. In other words, cultivation or inoculation is necessary to prove the presence of the bacilli during this period. It will be seen that Métin's results are not quite in accord with those of Gotschlich already referred to.

Famine and its Cost.—The Viceroy of India, in a speech recently delivered before the Council, gave some figures of the cost of the late famine in that country. According to Lord Curzon, the famine has affected at least one quarter of the population of India, and even yet 2,000,000 people are receiving relief. Five hundred thousand deaths have been caused by the famine, and the loss of the crops meant a total money loss of about \$250,000,000, a sum which does not include the value

of the cattle lost. A charity fund of 854 lakhs or rupees had been expended at the end of August.

It has been said by some members of the cold-blooded school of political economists, that the English rule in India is largely responsible for the immense overpopulation of that country. In olden times the Hindu population was kept down by famine, war and pestilence, so that the country was rendered more inhabitable for the fortunate survivors. The English, from humane motives, have endeavored to mitigate these three evils, with the result that there is no adequate relief from surplus population. Lord Curzon's figures suggest that this recent famine is possibly an illustration of one of the laws of population. In a densely peopled country any disturbance of the food-supply means starvation and death for many persons. Those social scientists who claim that a dense population is an evidence of national welfare and a promise of national progress, must overlook some of the frightful penalties paid by a country which, like India, is overpopulated and underfed. There should be a golden mean somewhere between population and the food-supply without the necessity of a reliance upon war, pestilence, and famine, and preventable disease.

Spasmodic Sneezing as a Manifestation of Whooping-Cough.—Whooping-cough may be considered a spasmodic neurosis, dependent upon the activity of a specific microorganism, possibly the bacillus isolated by Czaplewsky and Hensel and others, exerting its effects, perhaps through the intermediation of toxins, upon the muscular structures of the larynx, and giving rise to the characteristic inspiratory stridor. The vomiting that so frequently occurs, often independently of the succussion due to the cough, may likewise be a result of nerve-intoxication. In rare instances the cough and laryngeal spasm have been replaced by spasmodic sneezing, and a case in which this condition was present has recently been recorded Szegö (*Archiv für Kinderheilkunde*, 29 B., 3 and 4 H., p. 186). The patient was a boy, three years old, whose younger brother was suffering from an attack of whooping-cough and who was himself seized with catarrhal symptoms, of which coryza and sneezing were the most conspicuous. On removal of the clothing for purposes of examination, the child held its breath and became red in the face, but instead of giving vent to the expiratory spasmodic cough, it was seized with a paroxysm of sneezing. The termination of the attack was attended with the discharge from the nose of a copious amount of viscid mucus. The sneezing was sometimes associated with vomiting. In spite of the absence of laryngeal symptoms, however, laryngoscopic examination during the continuance of the attack disclosed the presence of laryngeal spasm. There were present also tracheobronchial catarrh, emphysema of the lungs and nasal catarrh of moderate

degree. The treatment consisted solely in exposure to the air at the seaside, and recovery gradually ensued. If, as has been indicated, the symptoms of whooping-cough are to be attributed to the toxic products of a specific microorganism, it would not be difficult to understand the transfer of the seat of the manifestation from the laryngeal to the nasal mucous membrane.

The Disease of the Doctor.—It is an accepted belief with many lay people that a physician spends the greater part of his existence in the contemplation of tragedy, and it is often a matter of surprise that under such depressing circumstances he maintains a reasonably contented disposition. It is not often realized that the life of the medical man may be itself a tragedy, rendered more acute by his knowledge of the diseased processes working toward his own destruction. Striking examples are known to all of us. It was only recently that a young physician of great promise, in charge of one of the European sanatoria for the treatment of pulmonary tuberculosis, and himself afflicted with the disease, undertook a careful scientific study of a remedy that had been suggested by a medical man, and heralded by other eminent practitioners as almost a specific for his disease; this was the inhalation of the gas arising from wood in the process of digestion by sulfuric acid, and known as lingo sulfite. His work was of the most careful nature, and included experimental investigations upon animals, and clinical investigations upon human beings. It can readily be imagined with what hopes he undertook his task! At the end of his article he is forced to conclude that the remedy is worthless, and he proved this by dying before his paper was published.

Surgical Treatment of Gallstones.—Maurice Richardson (*Chicago Medical Recorder*, September, 1900) points to the contrast between the great mortality of old and neglected cases of gallstones and the small mortality of recent ones that have been operated upon, and says that, could the surgeon start in where the physician did there would be a sound basis for argument; still one can compare large groups of cases which have been treated first medically with the same groups treated later surgically, and thus obtain a basis of comparison. The fallacy of this, however, lies in the fact that the surgeon treats only patients in whom medical treatment has failed, and who are reduced by prolonged suffering, while medical results are usually based upon a single gallstone attack subsiding coincidentally with rather than as a result of medical treatment. He bases his paper upon an analysis of 150 cases in which the question of operation for gallstone was raised and upon upward of 100 explorations; he reports a total of 23 deaths, of which 7 took place after exploration for malignant disease, and 13 after the removal of gallstones. In 3 fatal cases no operation was performed; these were very severe cases, the patients suffering from the prolonged gallstone lesions. In several cases operation was performed as a last resort; in no case of simple cholelithiasis did death occur and there were many recoveries after the most severe operations when the patients were reduced by prolonged suffering. He concludes that in hospital as well as in private cases mortality in operations has been due almost entirely to local changes and to general systemic depression, caused by prolonged retention of invading gallstones. He has had no deaths from which operations were performed early and upon the strong. [G.C.C.H.]

Correspondence.

A CASE OF ANESTHESIA BY THE SUBDURAL INFILTRATION METHOD.

By L. E. SCHMIDT, M.D.,
of Chicago, Ill.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE patient was 63 years old and was brought under my charge September 10, 1900. After preparing the bladder for 3 days and meanwhile examining the patient most carefully, I decided to use this subdural method of anesthesia. Theoretically it appears to be especially adapted to the operative work on the bladder, prostate gland, seminal vesicles, and other structures, whether within the male or female pelvis. As the patient was badly nourished and completely exhausted from the great pains which this condition caused, I was more convinced that it would be the ideal anesthetic to use. Complete loss of sensation of pain was noticed 10 minutes after the injection of 15 minims of a 2% sterilized solution of cocain into the spinal canal between the second and third lumbar vertebrae. The technic of the suprapubic operation remained the same. The operation required but 15 minutes, yet the anesthesia remained for over 60 minutes.

From the foregoing it is very apparent that this method can be employed with advantage in those cases whenever the conditions are as described in my case. From this I mean to infer that it would be perfectly proper to use this form of anesthesia in the class of cases cited, including those operated upon by the Bottini method. It is just here that this method would be invaluable, when this operation is often indicated, yet when we hesitate to give either chloroform or ether, and when we cannot always get complete anesthesia by applying cocain, no matter of what strength, or what other local anesthetic is used to the mucous membranes of the bladder and urethra.

MEDULLARY NARCOSIS.

By CHARLES ADAMS, M.D.,
of Chicago, Ill.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

LIKE the Athenians of old, the medical profession of today seems to run after new things only, apparently ready to forsake old and well-tried means for any novelty of procedure. It is possible that within 10 years all operations upon the portion of the body lying inferior to the costal arches may be performed under medullary narcosis; further, that general anesthesia by inhalation may be superseded by anesthesia of the operated region effected by the production of temporary paralysis of sensation by means of local agents. We are ready to adopt the new method when its positive advantage and greater degree of safety as compared with the old shall have been demonstrated, but until such demonstration shall have been made we are disposed to make the best use possible of the enormous amount of experience accumulated in the use of chloroform and ether.

As regards the question of medullary narcosis, recently brought prominently before the Thirteenth International Medical Congress, I believe a conservative stand should be taken. I do not believe that a sufficient amount of evidence exists as yet to warrant anything like endorsement of the new method. A careful examination of the reports will show

that the use of cocain in the subarachnoid space is not untended by danger, and, to say the least, certain symptoms, exceedingly unpleasant if not serious, followed its use in a large proportion of the cases reported. Thus, M. Severeanu, of Bucharest, after using the method 70 times, says, "In all the cases he observed a general weakness lasting one or two days, and sometimes causing great anxiety. There was very frequent vomiting, with headache, which was generally very severe. Independently of the dangers of the use of cocain, he finds there is a very serious inconvenience attaching to this particular procedure—namely, that it allows the patient to witness the operation." "He found it difficult to combat the alarming symptoms that sometimes occurred, although he had recourse to injections of caffein, ether, and artificial serum."

M. Tuffier, of Paris, reported upon 125 cases, of which 58 were laparotomies. "The phenomena which follow the injection are nausea, which may go on to vomiting when too large a dose has been injected, pallor of the face, respiratory distress, increase in the frequency of the pulse (from 90 to 120) on the day after the anesthesia, there may also be some vomiting, and more or less violent headache, lasting 15 to 24 hours, is practically always observed." The most common after-effect is vomiting, or a chill, or an elevation of temperature from 38° to 39° C. This temperature is short-lived, lasting 10 to 20 hours at the most.

Five of the 125 patients died, but M. Tuffier is satisfied that the anesthetic could not be held responsible for the result in any of the cases. One reporter says: "The death of four is easily explained apart from the anesthesia, the fifth died with symptoms of asphyxia. Necropsy in this case showed a mitral insufficiency with a marked congestion of both lungs," and then adds, "Cardiac disease is not a contra-indication."

M. Racoviceanu-Pitesci, of Bucharest, after an experience of 125 cases, does not believe that this method can replace chloroform-anesthesia. In 80 of his cases, light symptoms of intoxication ensued, lasting from 12 hours to 5 days, and 3 patients showed symptoms of intoxication that endangered life. He further stated that he knew of 2 cases in Roumania in which death had followed cocain-anesthesia by injection in the lumbar region.

Bumm and Kreis report the use of medullary narcosis by cocain in 6 cases of confinement, stating that the drug caused no bad symptoms, save a little cephalalgia, vertigo, and nausea in one patient.

Marx, of New York, reports (*N. Y. Med. News*, August 25, 1900) five confinements under the cocain-anesthesia, and is loud in his praises of its effects in such cases. He says: "The cases are too few to justify absolute deductions, yet they are sufficient to warrant me in stating that in the lumbar cocainization we have a method which is of the greatest value in producing analgesia, which checks almost entirely the pains of labor without, as far as personal experience goes, the least danger to mother or child." Further on the report reads: "Disagreeable, although very evanescent, features frequently occur. In fact, none of my patients escaped without some evidence of general disturbance, such as nausea, vomiting, severe headache, throbbing and fulness in the head, slight increase in the pulse-rate, chilly sensations, and elevations of temperature up to 103° F. on the evening of the day of operation." These symptoms Marx believes to be due to a disturbed intraspinal pressure, as similar symptoms were observed in a case in which salt-solution was used by mistake for the cocain-solution.

Although most of my information has been collected from the telegraphic reports of the meetings at Paris, there is such striking uniformity of statement as to the after-effects of the drug that I may feel assured that I am justified in forming an opinion on the evidence as above presented.

Speaking frankly, What is there alluring about this new method? Why should it be preferred to anesthesia by chloroform or ether? Is there anything attractive about it beyond its novelty? We may leave the obstetric cases out of consideration at once, for thousands of women have been given painless labors by the use of chloroform *without* severe headache and elevation of temperature to 103° F. on the evening of the day of operation from the anesthesia.

As regards the surgical cases, it would seem, from the presented evidence, that besides the "inconvenience," as Severeanu puts it, of the patients' witnessing the operation, the after-effects compare unfavorably with those following the skilful use of ether or chloroform.

Other objections to the use of this method are the risk of infection in the minor operation required for the injection of the cocain-solution into the lumbar subarachnoid space, and, from the fact that the entire amount of the anesthesia is used at once, further effects can not be prevented by stopping the administration of the agent.

I notice the absence of oxygen by inhalation from the list of agents used to combat the troublesome symptoms produced by the cocain-injection. Undoubtedly the principal reason for the active search for, and the readiness of the profession to adopt, new methods of anesthesia lies in the unsatisfactory results too often observed in the use of the well-established agents, chloroform and ether.

DR. JACOBI UPHELD.

By GEORGE METZLER, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

SHORTLY after my return from Europe a medical friend told me of the criticism of Dr. Jacobi's address before the International Medical Congress in Paris. He said that it had been condemned as being an apology of American medicine. Today I read the address of Dr. Moyer before the Mississippi Valley Medical Association containing his sweeping condemnation of Dr. Jacobi's address. I consider this criticism of Dr. Jacobi unjust and an act of great ingratitude. I am unaware whether Dr. Moyer was present at the general meeting in the amphitheater of the Sorbonne; but I know that of the American members registered, very few attended the meetings.

I have not seen Dr. Jacobi's address in print; but I stood very close to him when he delivered it. Its general character was such that the American profession may be justly proud of it. I doubt that the American profession possesses many members capable of delivering an address before such an assembly in such a manner. His French was elegant and faultless. But, aside from this otherwise very important factor, what was the quintessence of his address? It was this: that American medicine had kept pace with the development of medicine in Europe. (I write from memory.) Fifty years ago there was hardly any pathologic anatomy taught in the universities of Germany. There was Rokitan-ski in Vienna and Virchow in Würzburg; that was all. Today in all the better class of American schools the student has to attend a rigid laboratory course, and the Ameri-

can student works while he attends college. Today our journals and our books are the peers of the best journals and books in Europe.

I abstain from citing other passages from this great address, which only a philosophically trained mind could compose, whose conception of what the German calls *Weltanschauung* is far above the common-place. I write this despite the fact that my politico-economic belief differs from that of Dr. Jacobi.

The applause he received was general, enthusiastic, and second to none that was given the most distinguished delegate to the congress. *And it was justly earned.*

Would that others, who perhaps today condemn Dr. Jacobi, had kept their "papers" in their trunks instead of disgracing American medicine by reading them in section meetings.

I still see the grim smiles on the face of Sir Dyce Duckworth, who presided one morning over the section of *pathologie interne*, when a certain paper was read by an American. "He knew it all!" Frerichs, von Mering, Minkowski, Lepine, Chauveau, Kauffman, von Noorden—they were but babes compared with this great man. And there were others of the same type.

ADHESIVE PLASTER IN THE TREATMENT OF WOUNDS.

By EVAN O'NEILL KANE, M.D.,
of Kane, Pa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In your last issue appears a letter censuring a correspondent for advocating the employment of adhesive plaster in the treatment of wounds; it is claimed that this treatment is not in accordance with modern methods of aseptic surgery. I beg to state that I fail to agree with the writer. In hospital and outside practice much of my surgical work of the last three years, comprising over 1,000 operations, a large portion of which were abdominal sections, more than 100 being for appendicitis, I have used strips of adhesive plaster largely for the apposition of the edges of the skin-incision with the most gratifying results. These results could not have been obtained as well by any other method. The danger of stitch-abscess infection is avoided, also the distress occasioned by stitch-irritation, and the pain of their withdrawal. I always sterilize my adhesive strips in a steam sterilizer and brush them over lightly with chloroform before applying. Because we used adhesive plaster before the advent of aseptic surgery is no reason why we should not continue to use so useful a material now. Are we so much wiser than our fathers that we must abandon all the learning of the past?

A BAD ADVERTISEMENT.

By D. H. MURRAY, M.D.,
of Syracuse, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

It seems to me that R. L. Polk & Co. exhibit an unlimited amount of assurance in asking the medical profession of the United States and Canada to use their offices as billboards for the exclusive advertising of a proprietary medicine and in addition ask the members of the profession to pay \$6.00 each for the privilege. If this Medicine Company desires to advertise directly to sick people who are already in a physi-

cian's office, in immediate competition with him, they ought to be glad to furnish this "Physician's Directory" free to any physician who will allow his office to be used for such a purpose.

No other book in my library has such an advertisement on it, and it makes this one all the more prominent.

My patient sits down to consult me for some trouble that is causing him pain; he is facing my bookcase; he sees most prominent there, a four-inch aluminum bronze-lettered combination display advertisement—"If there's pain—that's enough."

I should have said he would have seen it had I not pasted a piece of leather over it.

Of course this is a good stroke of business on the part of the medicine firm and also on the part of Polk & Company, who no doubt received a handsome sum for this particular space.

I feel that any firm who are asking favors of the medical profession, and who at the same time offer such an insult, ought to be "boycotted," for they have practically said that we will stand any effrontery without knowing enough to resent it.

Personally, I desire to record an objection.

DESIGNATION OF THE OPERATION OF ROUND LIGAMENT VENTROSUSPENSION OF THE UTERUS.

By D. TOD GILLIAM, M.D.,
of Columbus, O.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In your issue of October 20 I find a statement from Dr. Carl Beck, of New York, in which he claims that I published a description of his operation in *every detail*, but failed to give him credit for the same. In the article referred to by Dr. Beck I was giving a description of my own operation, which in so far from tallying with the Beck operation *differs* from it in every detail. The only thing in common is the inclusion of the round ligament in the abdominal wall. If Dr. Beck can establish priority for this very important feature of the operation he is entitled to credit for it. I got my suggestion from Ferguson and gave him due credit in my first report of the operation in the *American Journal of Obstetrics*, March 1900. I had never heard of the Beck operation until I saw it in the same journal six months subsequently. My operation and the Beck operation are as distinct in detail as the Alexander and Kellogg operations.

Insufficiency of Left Auriculoventricular Orifice of the Heart.—In an article in the *Postgraduate* for September, 1900, Wm. Henry Porter says that organic and the so-called functional insufficiency at the left auriculoventricular orifice may be easily differentiated during life, not by their rational or physical signs, but by an appropriate line of treatment. If the cause of the so-called functional murmur is deficient innervation, by giving such remedies as will restore the nerve-power, the signs and the symptoms will quickly disappear, all regurgitation be prevented, and the patient relieved from all the unpleasant symptoms. On the other hand, when due to a defective nutrition, with incomplete innervation and irregular muscular action, a building up of the cardiac muscles, as can be done with proper dietetic and therapeutic conditions, the murmur will disappear. When the physical signs are due to positive lesions in the valve segments, then the physical signs will not disappear, but will often become more pronounced. Even if the murmurs do not disappear much can be accomplished in the way of improving the action of the heart.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended November 10, 1900:

Monday, November 5—Academy of Surgery.

Wednesday, November 7—College of Physicians.

Thursday, November 8—Pathological Society.

Charitable Bequests of \$10,000 to Philadelphia institutions are made in the will of the late Sallie C. Stout of this city.

Pennsylvania Hospital.—Dr. Alfred Stengel has been elected one of the physicians to the hospital to succeed the late Dr. Jacob M. DaCosta.

The Harrisburg Hospital is to be enlarged and improved and some of the old buildings replaced by new ones with all the modern appliances.

The Ogontz Hospital for the Insane near Philadelphia has applied for a charter. This institution is intended to relieve the overcrowded condition of the Norristown Hospital.

Diphtheria prevails in West Philadelphia, particularly in the Thirty-fourth Ward, where 30 cases were reported in one week. The Bureau of Health has ordered the school-houses fumigated.

Philadelphia Hospital.—The Bureau of Charities has appropriated \$130,000 for the erection of new buildings at the almshouse. The insane department will be enlarged and a building erected for the treatment of infectious diseases.

St. Agnes' Hospital, Philadelphia.—Dr. Joseph M. O'Malley was recently appointed visiting physician to succeed Dr. J. P. Crozer Griffith, resigned, and Dr. Edwin N. Barnhill and Dr. Francis D. Patterson were appointed surgeons in the surgical out-patient department.

University of Pennsylvania.—Owing to the fact that Dr. Edward Martin has been elected clinical professor of surgery, a vacancy arises in the clinical professorship of genitourinary diseases. Candidates may apply to Rev. J. Y. Burk, 400 Chestnut Street, before November 10.

An Aged Man.—Edward Henry died in Pittsburg, Pa., October 27. It is reported that he was born a slave in Culpeper, Va., in 1784, and was therefore 116 years old. He was married 5 times and is survived by his fifth wife, by whom he had 13 children. He is said to be the father of 60 children.

The New Jersey Sewerage Commission has given notice that the property-owners along the Navesink River, near Red Bank, must cease polluting the river on and after June 1, 1901. The town of Red Bank was at the same time ordered to provide a new sewerage-disposal plant by October 1, 1901.

Petition for a Municipal Hospital.—The City Council of Camden, N. J., failed to comply with the request of the Board of Health for the establishment of a municipal hospital. The medical profession of that city has presented a petition renewing the request and pointing out the urgent need of such an institution.

Pittsburg Episcopal Hospital.—An addition will soon be built to this institution, built and supported by the proceeds of that part of the Aspinwall estate that was set aside by the late Mrs. Aspinwall as a legacy to the Episcopal Hospital for the purpose of maintaining a ward for "poor white female orphan children who have been ill and are convalescent."

Druggists and the State Board.—It is reported that the State Pharmaceutical Examining Board has summoned several hundred retail druggists of Philadelphia to pay a fine of \$10 for neglecting to exhibit in view of their customers renewal receipts for the payment of their State registration fee. At a hearing on October 29, 5 of the men paid a fine of

\$10 and \$2.50 costs. The hearing of others was postponed until November 12. The druggists say that they did not know that the law required them to frame and expose the receipt in a conspicuous place. The Retail Druggists' Association intends to resist the payment of the fines.

The Asylum Nurse.—In an admirable paper entitled "A Plea for the Asylum Nurse," Robert Howland Chase, M.D., superintendent of the Friends' Asylum at Frankford, after paying a glowing tribute to the self-sacrificing work of trained nurses in general, to those in hospitals and on the battlefield, makes a strong plea for young women to become trained in nervous and mental nursing, which he considers requires special training and superior ability. He says: "Nursing the nervous and insane is growing into a profession which in its tendencies is progressive, and, when properly pursued, will lift the worthy nurse above the common toils, in proportion as she devotes her energies to it."

Berks County Medical Society.—At the October meeting of this society Dr. A. B. DUNDORE read a paper on the **Old and new obstetrician**. He spoke of the obstetrician of 30 years or more ago, when soap and water were the only antiseptics used, and he believes that the mortality was as low then as it is now. Dr. F. W. FRANKHAUSER read a paper on **Fracture of the skull**, with the report of a case. He said Mumford in his analysis reported 300 cases of fracture of the skull treated at the Massachusetts General Hospital. Of these 279 were compound and only 21 were simple fractures. Of the 300 patients, 175 died. The writer pointed out the difficulties in diagnosing the simple fractures. The mortality of fracture of the base of the skull was 80%; of the vault 37.5%. He dwelt on the rarity of septic infection of those wounds, and insisted that the uninjured dura mater presented a strong barrier against it. The writer urged the necessity of trephining in every case of depressed fracture whether or not it is accompanied by an external wound or grave symptoms. He claims that in children especially the fracture will cause epilepsy and mental defect, and that one should operate at once and should not wait for symptoms of compression.

Vital Statistics of Philadelphia for the week ended October 27, 1900:

Total mortality	Cases.	Deaths.
Disease.		
Inflammation of appendix 1, bladder 3, brain 5, bronchi 5, kidneys 14, larynx 1, heart 1, lungs 41, pericardium 1, peritoneum 3, pleura 2, stomach and bowels 25		102
Lungs—tuberculosis of 46, hemorrhage of 1		47
Debility 5, marasmus 22, inanition 13 . . .		40
Heart—disease of 24, fatty degeneration of 2		30
neuralgia of, 4		26
Paralysis 9, apoplexy 17		21
Uremia 13, Bright's disease 5, diabetes 3 . .		14
Diphtheria	119	12
Casualties		
Carcinoma of face 1, jaw 1, liver 2, neck 1, stomach 3, uterus 2, sarcoma of arm 1 . .		11
Bowels—ulceration of 4, obstruction 4 . . .		8
Brain—diseases of 1, congestion of 3, dropsy of 1, hemorrhage of 1, softening of 1 . . .		7
Convulsions		7
Typhoid fever	55	7
Diarrhea 5, dysentery 2		7
Old age		6
Septicemia 4, pyemia 1		5
Asthma		4
Croup 2, membranous 1		3
Sclerosis, arterial		3
Malaria		3
Sore mouth		3
Liver—diseases of 1, cirrhosis of 2		3
Scarlet fever	35	1
Abcess of bladder 1, abortion 1, alcoholism 1, anemia 1, cyanosis 2, drowned 2, epilepsy 1, intermittent fever 1, fistula 1, gangrene of leg 1, senile 1, hernia 2, locomotor ataxia 1, suicide—hanging 1, syphilis 2, teething 1, unknown coroner's case 1.		

Memorial services were held October 28 in the Tabernacle Presbyterian Church, Philadelphia, commemorating the life and martyrdom of George Yardley Taylor, M.D., of Paoing Fu, China. It is feared that the son of Dr. E. B. Hodge perished at the same time. Dr. De Forest Willard

and others made addresses. Dr. Taylor by his skill and devotion had saved so many lives that high native officials believed he would be spared, but the very esteem in which he was held increased his value as an offering to the Chinese deities, and his head was laid on a Boxer altar on June 30. He was a graduate of Princeton and of the Medical Department of the University of Pennsylvania. His intellectual precision and unusual memory, his skill as an operator, his powers of endurance, his courage, faithfulness, gentleness and unselfishness peculiarly fitted him for the calling of a physician, and his remarkable gifts as a linguist enabled him to use his scientific knowledge with the utmost effectiveness. His rare modesty and absolute singleness of purpose made him shun the prominence which his brilliant abilities could have so easily won. Such men do not die. Dr. Taylor lives still in two hemispheres as a moral force to which martyrdom has added an impetus that will carry his influence far into the future.

Pittsburg Academy of Medicine.—At a meeting, held October 15, Dr. E. W. DAY reported a case illustrating the resistance of the facial nerve to contiguous inflammation. Dr. J. H. ANDERSON read a paper entitled *Why do we so frequently have relief from pain and other symptoms following operation for exploration of the kidney where calculus, nephroptosis, pyelonephritis, and tumor are suspected and not found.* A case was cited in which renal calculus was suspected by reason of renal colic, hematuria, and bacteriuria without decomposition of urea. No calculus was found on exploration, but the kidney was enlarged and firmly fixed, with hyperplasia of the perirenal, cellular and adipose tissue. The manipulation and freeing of the adherent tissue was followed by the entire relief of all symptoms in less than two weeks. The atrium of infection was considered: 1. In descending infections to be hematogenous after suppurative diseases with suppurative foci in kidneys, and in injuries and diseases of the alimentary canal with pure cultures of the *Bacillus coli communis* in the urine. Experiments of Posner and Lewin show the frequent existence in kidney-lesions of this bacillus. The theories of the Guyon school, of Rosving, Melchior, and Moullin were considered. 2. In ascending infections, from a focus in the urethra or bladder by the lymphatics ascending the ureter to pelvis and capsule and intertubular portions of the kidney. 3. Infection through a standing column of urine in urethral obstruction, the infection following the mucous membrane. 4. Infection by contiguity, as in psoas abscess, etc. In the case cited, there was probably a lymphatic infection with passive hyperemia, causing renal colic and hematuria. This was relieved by freeing the capsule and perirenal tissue, permitting drainage of the lymphatics. In the treatment of bacteriuria originating in the bladder, 1½ ounce of 2% silver nitrate solution is injected and permitted to remain 2 minutes, followed by 1½ ounces of sterile water. If the infection be from a higher point, give 2 quarts of water and 12 grains of salol daily, in order to dilute culture-media and render it antiseptic if it be possible. In every case of persistent renal pain with hematuria or bacteriuria, exploratory operation should be resorted to. In discussion Dr. ADOLPH KOENIG said that if the conditions thought to exist in Dr. Anderson's case were present, it was difficult to understand how they should disappear so suddenly without leaving a kidney more or less diseased. Dr. WILLIAMSON reported at length a case of chronic nephritis in a man, with double pleural effusion, ascites, and general anasarca, and loss of 100 pounds in weight, under treatment for 2 years. The patient has made a remarkable recovery, being in good general condition at present. He has been most benefited by a pill of blue mass, digitalis, squills, and hyoscyamus.

NEW YORK.

Scarlet fever is epidemic at Palmyra, N. Y. In all about 40 cases have been reported.

Clara Barton, of the Red Cross Society, is reported dangerously ill in Galveston, Texas.

Hospital Donations.—The Episcopal Eye, Ear, and Throat Hospital, Washington, D. C., was the recipient of generous donations, October 27.

The New York State Association of Railway Surgeons will hold its annual meeting at the Academy of Medicine, New York City, November 15, 1900, under the presidency of Dr. J. L. Eldy, of Olean.

Charity.—John D. Rockefeller, Jr., has decided to erect a 5 story building, to cost \$100,000, at Tenth Avenue and Fiftieth Street, New York, to be devoted to the educational and social needs of poor people who live in the neighborhood.

New York Skin and Cancer Hospital.—The governors of this hospital announce that Dr. L. Duncan Bulkley will give a third series of **Clinical Lectures on Diseases of the Skin** in the hall of the hospital on Wednesday afternoons, commencing November 7, 1900, at 4:15 o'clock. The course will be free to the medical profession.

Sanatorium for the Tuberculous.—In a paper on "The City and Its Consumptive Poor—A Plea for a Municipal Sanatorium Outside of the Corporate Limits," read recently before a section of the New York Academy of Medicine, Dr. Alfred Meyer said that such an institution could be built for \$3,000,000 and maintained with \$100,000 a year. He estimated the number of tuberculous individuals in New York to be about 30,000.

New York Eye and Ear Infirmary.—At the annual meeting of the Board of Directors of this institution recently, the annual report showed that for the year ended September 30 there had been treated in the dispensary department 30,878 new cases in the eye service, 9,710 in the ear, and 7,096 in the throat; and that 2,257 patients had been treated in the hospital ward, representing 20,734 days of care. The treasurer's report showed a balance of nearly \$4,000 in favor of the institution after all bills were paid. During the year the permanent fund has been increased by \$65,000.

Midwife Held for Causing an Infant's Blindness.—According to the *Boston Medical and Surgical Journal*, Mrs. Barbara Harprecht, of New York, a midwife, has been held in \$600 bail for trial, charged with causing, by her negligence, the blindness of an infant at whose birth she officiated last spring. This is said to be the first case of the kind in recent years in which the Health Department has been able to get the evidence in such a shape as to enable it to proceed against the responsible person, although it is well known that a large part of the blindness existing at present has been caused by neglect and improper treatment during early infancy. The section of the Penal Code under which the woman will be tried provides that when the eyes of a young child whose birth has been attended by a midwife become affected, the midwife is forbidden to treat or prescribe for the condition, but must either notify the Board of Health or secure the services of a physician. Violation of the statute is punishable by a fine of \$250 or 6 months' imprisonment, or both.

NEW ENGLAND.

The Middlesex East District Medical Society of Massachusetts observed its fiftieth anniversary, October 23, the address of the occasion being given by Dr. S. W. Abbott, Secretary of the State Board of Health.

The Supreme Court of Massachusetts has decided that physicians under the Massachusetts statutes are not liable for negligence in erroneously certifying a person insane or inebriate, provided they do so in good faith and without malice.

The Farren Memorial Hospital, built at Montague City, Mass., by B. N. Farren, of Philadelphia and Montague City, as a memorial to his son, was dedicated October 23. The building is a handsome brick structure, with stone trimmings, modern in every particular. It will be in charge of the Sisters of Providence, and no one will be excluded from the institution on account of poverty.

Harvard University has a medical inspector whose duty it is to care for the health of the students. The students to whom Dr. Bailey, the present inspector, will be required to give his attention this year will number about 3,500. His work will be materially assisted by the new infirmary which is to be built under the terms of a gift of \$100,000 to the

university by James Stillman of New York. Another gift that has followed the appointment of the medical visitor to the University has been the \$156,000 to establish a professorship of hygiene.

Thurber Medical Association.—This society held its forty-seventh annual meeting in Milford, Mass., on October 4. The following officers were elected: President, N. C. B. Haviland, of Holliston; vice-president, Ralph C. Fish, of Hopedale; secretary, J. M. French, of Milford; Treasurer, Le Grand Blake, of Milford; librarian, C. D. Albrow, of Milford; orator for 1901, N. C. B. Haviland. A prize of a standard medical work was awarded to J. M. French, of Milford, for a paper on **The treatment of acute croupous pneumonia; a collective investigation report**, which was by vote of the members decided to be "the most meritorious paper read before the society during the year by an active member." The annual address was delivered by Dr. N. W. Browne, of Blackstone, on **The lights and shadows of a physician's life**. After dinner toasts were proposed to the Clergyman, the Alienist, the Lawyer, and the Thurber Medical Association, with responses by the members and invited guests, of whom a considerable number were present.

CHICAGO AND WESTERN STATES.

The American Public Health Association held its first meeting at Indianapolis, Ind., October 23. A report of the meeting will appear in our next issue.

Smallpox on Shipboard.—A case of smallpox on board the *City of Seattle* carrying over 200 passengers, caused her detention for 2 weeks at the quarantine station near Vancouver City.

The Illinois Home for Epileptics has moved to its permanent location, 3240 Lake Park Avenue, Chicago. The home is a charitable institution and is open at all times for the reception of emergency cases.

The Merritt Hospital, Oakland, Cal.—The decision of the lower court has been sustained by the United States Supreme Court, and the \$500,000 devised by Mrs. Catherine M. Garcelon thus made available for the erection of this hospital.

Smallpox in Montana.—There are more than 40 cases of smallpox in the hospital at Butte, Montana, and the health officer has instructed the police of the city to enforce compulsory vaccination and arrest all persons who fail to show the proper certificates.

Defective Eyes.—The physicians of the health department of Milwaukee who examined the pupils of the public schools report that out of 19,618 children examined, 5,055 cases of defective eyes were found, of which number 3,209 were girls. There were 1,419 cases of defective hearing.

Suit for Damages.—The house physician of St. Vincent's Charity Hospital, Cleveland, Ohio, the Sisters of Charity, Mother Superior and Ignatius F. Horstmann are defendants in a suit for \$10,000 damages entered September 29 by a patient who claims that she was burned by hot-water bags while in narcosis after operation.

The Northwestern Wisconsin and Fox River Valley Medical Associations held a joint meeting in Oshkosh, October 23. Papers were read by Drs. J. G. Hirth, W. H. Nielson, and F. Shimonek, of Milwaukee; Emil Rees, Byron Robinson, and L. Hektoen, of Chicago; V. T. Marshall, of Appleton; and C. J. Coombs, of Oshkosh.

Free Care for Epileptics.—The Illinois Home for the Treatment and Care of Epileptic Patients is the only institution in the State where the treatment of these unfortunates is free. The object of the home is the establishing of an epileptic colony and the erection of a building for this large class of patients, with farms, workshops, a theater, reading-room, gymnasium and equipment for restoring the mental faculties of curable epileptics, and to give a miniature world to incurable epileptics. Incarceration of epileptics in insane asylums and the abuse of persons who fall in a fit on public streets are to be prevented. In receiving and treating patients no exception will be made as to color, creed, race, or religion.

Home for Disabled Railroad Men.—At a meeting of the Brotherhood of Locomotive Firemen, held recently at Des Moines, Iowa, steps were taken for the establishment of a home for aged and crippled railroad men. The sum of \$9,000 was voted for this purpose. Other railroad organizations will be asked to assist in the maintenance of a home for railroad employees similar to those operated by the Masons and Odd Fellows.

"Oakland College of Medicine and Surgery" is the name of a new college to be opened in 1901 at Oakland, Cal. Clinics will be started by January 1. The course in the new college will be for 4 years and the entrance requirements will be fixed at a very high standard. The incorporators of the new college, who will serve as the first board of directors, are: Dr. Frank L. Adams, Dr. J. S. Eastman, Dr. Carl Krone, Dr. Hayward G. Thomas, and Dr. D. D. Crowley.

Medical Inspection of Schools.—Some members of the Chicago Board of Education are opposed to the medical inspection of children who attend the public schools on the ground of expense. Parents and friends of medical inspection, who regard it as a safeguard, are protesting to the Board from all parts of the city. During 3½ months of the last school year 76,000 examinations were made, and 4,539 cases of contagious disease discovered and excluded from the schools. Since September of the present year 510 contagious cases have been excluded.

Chicago Pathological Society.—Regular meeting, October 8, 1900. DR. LUDVIG HEKTOEN, president, in the chair. DR. S. E. MUNSON, of Springfield, Ill., read a paper upon **milk-supply**, discussing in particular the relation between milk-supply and tuberculosis. The recent literature bearing upon the subject was discussed, and the use of tuberculin and the slaughter of cows giving a reaction were advocated. The paper was discussed by DR. W. A. EVANS and DR. ADOLPH GEHRMANN. DR. EVANS spoke of the various measures advocated for the elimination of tuberculosis from herds of cows, and concluded by advising the killing of all tubercular cows, as has been urged by Virchow. DR. GEHRMANN referred to the measures taken by the Chicago Health Department relative to the detection of tubercle-bacilli in milk. The examination of a general milk-supply for the bacilli has been discontinued, and only the milk from individual cows is tested. The use of tuberculin is always recommended in any case where suspicion is aroused, in preference to the examination of the milk. The detection of pus in milk is considered sufficient evidence upon which to condemn it, even in the absence of tubercle-bacilli. DR. BROWN PUSEY demonstrated specimens of a **glioma of the retina** (so-called "neuroepithelioma"). He said that the present agitation of the subject of glioma of the retina undoubtedly is due to the article of Flexner, published August, 1891, and to the book of Wintersteiner, "Das Neuroepithelioma der Netzhaut," published 1897. In these publications particular attention was paid to the rosetts found in such tumors. Wintersteiner described the roset as composed of cells derived from the neuroepithelial layer of the retina; the wall of the central cavity of the roset, he considered, corresponded to the external limiting membrane of the retina, with rudimentary rods and cones projecting into the central cavity. Flexner and Wintersteiner, working independently, came to similar conclusions, and from these studies suggested the name neuroepithelioma retinae to replace the term glioma retinae. These conclusions have been accepted by many authorities; others have opposed them. Two facts have been particularly hard to explain when considering these tumors as new growths derived from the neuroepithelial layer of the retina. One is, that according to present views, such highly differentiated tissues do not form tumors; the other is, that gliomas arising elsewhere than in the eye have very similar rosetts. Dr. Pusey exhibited specimens from a tumor that was evidently removed in a very early period of its development. It showed the rosetts unusually clearly. For comparison he brought specimens procured when he was a student of Wintersteiner, and also specimens from the tumor on which Emanuel did his work,—the article published in the August number of *Virchow's Archives*. There is no doubt, according to the writer, that the cells of the rosetts of this tumor do in places split up into fibrous tissue—into neuroglia. He believed that his specimens

demonstrate that the rosetts are composed of cells which form neuroglia; in other words, that the suppositions of Flexner and Wintersteiner that these tumors are neuroepithelioma are incorrect, and that these tumors are, as was formerly believed, true gliomas. In the discussion Dr. M. HERZOG agreed that the tumor consisted of glia cells, and that if the blood could be demonstrated in some of the spaces, the picture would correspond to a glioma of the central nervous system. Dr. H. DUNCAN demonstrated specimens of **castration tumors** from swine, a disease characterized by a tumor or growth which appears as a rule after castration, occupying the position of the testicle. Similar growths occur, however, in other situations, and in the female, usually on the breast. A trauma of some kind invariably occurs previous to the appearance of the growth.

SOUTHERN STATES.

Typhoid Fever.—An epidemic of typhoid fever exists at Elkton, Md. Already 36 cases have been reported. Samples of water taken from the town reservoir were found to be good, but those from the wells very bad.

Medical Inspectors for Schools.—Congress is to be asked to provide 11 medical inspectors for the public schools of the District of Columbia, in conformity with the report of Health Officer Woodward on the need of frequent examination of the pupils. A salary of \$500 is to be paid the physicians appointed.

Richmond (Va.) News.—The first time an operation was performed in this city by the use of **cocain injected in the arachnoid space** of the spinal column was on October 16 at the Virginia Hospital, by Dr. Hugh M. Taylor. The patient had an extensive necrosis of the femur, which was scraped and chiselled out, pure carbolic acid injected into the marrow cavity and the wound drained with a large glass tube. The results, as far as anesthesia are concerned, were perfect; 15 drops of a 2% solution being used.

The Society of Ophthalmologists and Otologists, of Washington, D. C., held its first meeting of the season at the residence of its president, Dr. E. Oliver Belt, October 19. Dr. Belt exhibited a patient suffering with **pulsating exophthalmos** of 2 years' duration. Dr. Walter Wells reported a case of **nasal sarcoma**. Dr. J. H. Bryan read a paper on **facial paralysis due to middle-ear disease**. At a recent meeting of the Board of Governors of the Episcopal Eye, Ear, and Throat Hospital the medical staff reported that during the past 9 months 6,848 visits were made to the Hospital by 1,464 patients, 212 operations were performed, and 153 patients were received into the Hospital.

The Medical Society of Virginia.—The thirty-first annual meeting of the society was held at Charlottesville, October 23, 24, and 25. The president was Dr. Hugh T. Nelson, of Charlottesville. A special committee suggested the following names as those of physicians to be nominated to the Governor by the society for members of the State Board of Health: Drs. Paulus A. Irving and Landon B. Edwards, Richmond; L. E. Harvie, Danville; Rawley Martin, Lynchburg; Vernon G. Culpepper, Portsmouth; J. H. Neff, Harrisonburg; J. T. Graham, Wytheville. The suggestion was approved by the society. Honorary fellowships were conferred upon Dr. W. Richardson, of Boston; Dr. Edward Parker Davis and Dr. S. H. Musser, of Philadelphia, and Dr. Hugh T. Nelson, of Charlottesville. Notice was given of the purpose to erect a monument in the Capitol Square in Richmond in honor of Dr. Hunter McGuire. The society pledged a contribution.

MISCELLANY.

The Music Cure.—It is reported that the authorities of the Manhattan Asylum, Ward's Island, are now making systematic experiments with the music cure, and have thus far treated a dozen or more patients afflicted with melancholia, giving them concerts an hour long each afternoon with the harp, violin, and piano for instruments. They report after a month's trial that improvement is shown and that patients suffering from acute mania and hallucinations

show more mental alertness and cheerfulness, and that one patient has been assisted almost to recovery by the strains of the violin alone.

Status of Contract Surgeons.—The Comptroller of the Treasury has held that a contract surgeon in the U. S. army is neither an officer nor an enlisted man and is not entitled to the 10% increase in pay, under the Act of May 26, 1900.

Health-Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended October 27, 1900:

Obituary.—LAURENCE TURNBULL, of Philadelphia, October 24, aged 79. Dr. Turnbull was a native of Lanarkshire, Scotland. He came to this country when 12 years of age, and was graduated from the Philadelphia College of Pharmacy and the Jefferson Medical College. He was the first surgeon in this country to open the mastoid process for dis-

ease of that region. He was a member of many medical societies. Among his contributions to medical literature are: "A Biographical Sketch of Professor John K. Mitchell;" "The Electro-Magnetic Telegraph with an Historical Account of Its Rise;" "Defective and Impaired Vision, with the Clinical Use of the Ophthalmoscope;" "Clinical Observations on the Relief of Pain in Acute Affections of the Ear," and "A Manual of Anesthetic Agents and their Employment in the Treatment of Disease."—JAMES F. MAHONEY, of New York, October 15, aged 35.—PHILIP ROTH, of Newark, N. J., October 21, aged 36.—DAVID PELLMAN BOYER, of Philadelphia, October 14, aged 76.—JOHN MILLS, of Pana, Ill., October 16, aged 81.—JOHN C. BECHTEL, of Harrisburg, Pa., October 11, aged 49.—HIRAM GREENTREE, of Baltimore, October 23.—EDWARD R. SQUIBB, of Brooklyn, October 26, aged 81.—CAPT. BENJAMIN BROOKE, Assistant Surgeon, U. S. Army, at Radnor, Pa., October 18.—GEORGE A. MUEHLECK, of Philadelphia, October 15, aged 40.—MATTHEW J. GREER, of Philadelphia, October 27, aged 73.—JOHN P. DUDLEY, of San Jose, Cal., October 23, aged 50.—JAMES H. McNUTT, of Bowling Green, Mo., October 25, aged 70.—ALEXANDER H. JOHNSON, of Newark, N. J., October 25.—WILLIAM J. NELSON, at Middletown, N. Y., October 26, aged 40.—EDWARD ADDISON HERVEY, of Rossville, S. I., aged 76.

Changes in the Medical Corps of the U. S. Army for the week ended October 27, 1900:

BRUHL, CHARLES E., acting assistant surgeon, is relieved from duty at the headquarters of Second Artillery, Vedado, Cuba, and assigned to Hamilton Barracks, Matanzas.

PINTO, ALVA S., acting assistant surgeon, is granted leave of absence for 1 month, with permission to go beyond the limits of the division of Cuba.

PURVIANCE, Captain WILLIAM E., acting surgeon, will proceed to the Presidio, where he will report at the General Hospital for duty.

McLAUGHLIN, WHARTON B., acting assistant surgeon, is relieved from temporary duty at the Army General Hospital, Presidio, and assigned to temporary duty with troops on the Army transport "Grant," to sail for the Philippine Islands about October 16. Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

ROBERT, MERTON A., acting assistant surgeon, is relieved from temporary duty at the Army General Hospital, Presidio, and assigned to temporary duty with troops on the Army transport "Grant," to sail for the Philippine Islands about October 16. Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

CHAMBERLAIN, GEORGE E., acting assistant surgeon, is relieved from temporary duty at the Army General Hospital, Presidio, and assigned to temporary duty on the transport "Conemaugh" during the voyage of that vessel to the Philippine Islands. Upon arrival at Manila he will report to the commanding general, division of the Philippines, for assignment to duty.

BAUER, ALFRED, hospital steward, and 50 privates, hospital corps, Army General Hospital, Washington Barracks, will be sent, fully equipped for the field and for service in the tropics, to Brooklyn, N. Y., and will report to the commanding officer, transport "Buford," for transportation to Manila, P. I. Upon arrival there they will report to the commanding general, division of the Philippines, for assignment to duty in that division.

LEONARD, CHARLES L., hospital steward, Fort Columbus, will report, fully equipped for the field and for service in the tropics, to the commanding officer, transport "Kilpatrick," Brooklyn, N. Y., for transportation to Manila, P. I., and for duty with detachment of hospital corps privates aboard that transport. Upon arrival there he will report to the commanding general, division of the Philippines, for assignment to duty in that division.

REED, Major WALTER, surgeon, now in Washington, D. C., is detailed to represent the medical department of the Army at the meeting of the American Public Health Association, to be held at Indianapolis, Ind., October 22 to 26. He will proceed to Indianapolis in time to reach there on or before October 22, and upon the adjournment of the association will return to his proper station.

HYSELL, Major JAMES H., surgeon, is granted leave of absence for 2 months.

MUNSON, Captain EDWARD L., acting surgeon, is, on surgeon's certificate, granted 15 days' extension of leave of absence.

BECK, CARROLL D., acting assistant surgeon, is relieved from further duty at Fort Yellowstone, to take effect upon the return to that post of Acting Assistant Surgeon James B. Ferguson, and will proceed to San Francisco, Cal., and report to the commanding general, department of California, for transportation to Manila, P. I., where he will report to the commanding general, division of the Philippines, for assignment to duty.

JOHNSON, DAVID J., acting assistant surgeon, is relieved from duty at Plattsburg Barracks, to take effect upon the arrival at that post of First Lieutenant Henry Page, assistant surgeon, and will proceed to his home, Roxbury, Mass., and report by letter to the Surgeon General of the Army for annulment of contract.

LUDINGTON, P. L., acting assistant surgeon, will proceed from Omaha, Neb., to New York City, for assignment to duty as transport surgeon on the transport "Kilpatrick."

CARROLL, JAMES, assistant surgeon, is granted extension of leave of absence for 10 days, on surgeon's certificate.

VAUGHAN, MILTON, acting assistant surgeon, is relieved from further duty in the department of Eastern Cuba, and upon the expiration of his present leave will proceed from Little Rock, Ark., to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops destined for the division of the Philippines.

SCHLAGETER, HERMAN J., acting assistant surgeon, now at San Francisco, Cal., is relieved from temporary duty at Vancouver Barracks, and upon the expiration of his present leave will report to the commanding general, department of California, for assignment to duty.

WILSON, RICHARD, acting assistant surgeon, is relieved from further duty in the department of Eastern Cuba, and will proceed from Santiago, Cuba, to Washington, D. C., and report to the Surgeon-General of the Army for instructions.

FULLER, First Lieutenant LEIGH A., assistant surgeon, will report to the commanding officer, battalion of the Fifteenth Infantry, for duty and will accompany it to the department of Southern Luzon.

FULCHER, MARRON O., acting assistant surgeon, will report to the commanding officer, battalion of the Fifteenth Infantry, for duty and will accompany it to the department of Southern Luzon.

STUCKEY, HARRISON W., acting assistant surgeon, will report to the commanding officer, squadron of the Third Cavalry, for duty, and will accompany them to the department of Northern Luzon.

STREET, LIONEL A. B., acting assistant surgeon, will report to the commanding officer, Company E., battalion of Engineers, for duty, and will accompany them to the department of Northern Luzon.

ALLEN, H. E., acting assistant surgeon, will report to the commanding general, department of Southern Luzon, for assignment to duty.

FITZGERALD, CHARLES J., acting assistant surgeon, is relieved from duty in the department of Southern Luzon, and will report at convalescent hospital, Corregidor Island, P. I., for duty.

REYNOLDS, Major FREDERICK R., surgeon, is relieved from duty at the First Reserve Hospital, and will report for duty as chief surgeon, separate provost guard, Manila, P. I.

NEWTON, RALPH W., acting assistant surgeon, will report to the commanding general, department of Northern Luzon, for assignment to duty.

RENO, WILLIAM W., acting assistant surgeon, will report to the commanding general, department of Northern Luzon, for assignment to duty.

UNGER, ISIDOR M., acting assistant surgeon, will report to the commanding general, department of Northern Luzon, for assignment to duty.

MANN, HARRY C., acting assistant surgeon, will report to the commanding general, department of Southern Luzon, for assignment to duty.

BYRNE, JOHN B., acting assistant surgeon, is relieved from duty in the department of Mindanao and Jolo, and is assigned to duty in the department of Southern Luzon, where he is now on temporary duty.

LOWER, WILLIAM E., acting assistant surgeon, will report to the commanding general, department of Southern Luzon for assignment to duty.

McGRATH, PATRICK J., acting assistant surgeon, will report to the commanding general, department of Southern Luzon, for assignment to duty.

BAKER, WILLIAM P., acting assistant surgeon, will proceed to Iloilo, Panay, reporting to the commanding general, department of the Visayas, for assignment to duty.

MITTELSTAEDT, CHARLES B., acting assistant surgeon, will proceed to Iloilo, Panay, reporting to the commanding general, department of the Visayas, for assignment to duty.

O'NEILL, JOSEPH A., acting assistant surgeon, will proceed to Iloilo, Panay, reporting to the commanding general, department of the Visayas, for assignment to duty.

BRADLEY, HENRY H., acting assistant surgeon, is relieved from duty at Camp William H. Osborne, Idaho, to take effect upon the return to duty at that post of Acting Assistant Surgeon Jesse P. Truax, and will proceed to his home, Buffalo, N. Y., and report by letter to the Surgeon-General of the Army for annulment of contract.

Changes in the U. S. Marine-Hospital Service, for the week ended October 27, 1900:

BAILLACHE, PRESTON H., surgeon, to proceed to the purveying depot, New York, N. Y., as inspector. October 20.

GASSAWAY, J. M., surgeon, is granted 2 days' leave of absence from October 19, under paragraph 179, regulations.

STONER, G. W., surgeon, 3 days' leave of absence granted October 16 is amended so that said leave shall be for 2 days only. October 23.

COFER, L. E., assistant surgeon, will proceed to Philadelphia, Pa., and report to the medical officer in command for temporary duty. October 25.

FOX, CARROLL, assistant surgeon, to proceed to Portland, Ore., and assume command of the service. October 25.

BEAN, L. C., acting assistant surgeon, is granted leave of absence for 2 days. October 23.
 GREGORY, G. A., acting assistant surgeon, is granted leave of absence for 7 days. October 13.
 GAHN, H., hospital steward and chemist, is granted leave of absence for 20 days from November 12. October 17.
 ROEHRIG, A. M., temporary hospital steward and assistant chemist, is relieved from duty at San Francisco, Cal., and directed to proceed to the immigration depot, New York, reporting to Surgeon L. L. Williams for duty. October 19.
 SCHLAAR, W. F., hospital steward, upon being relieved by Temporary Hospital Steward and Assistant Chemist A. M. Roehrig, will proceed to Washington, D. C., and report at bureau for duty. October 19.
 MORGAN, D. H., passed assistant surgeon, is commissioned passed assistant surgeon from November 27, 1899.
 LEDBETTER, R. E., assistant surgeon, is appointed assistant surgeon from October 19, 1900.

Foreign News and Notes.

GREAT BRITAIN.

Physicians in Parliament.—At the recent election, 11 physicians were elected to Parliament and 10 medical candidates were defeated.

Death from A. C. E.—A death from this anesthetic occurred recently at Guy's Hospital. Cardiac failure was the alleged cause of death.

Lunacy Fees.—The Devonport Board of Guardians has decided that 1 guinea is too large a fee for the medical examiner in pauper lunacy cases.

Smallpox Among Returned Troops.—The *Kildonan Castle*, from South Africa, has arrived at Southampton with smallpox among the soldiers on board.

Typhoid Epidemic in Southwark.—No cause has as yet been found for this outbreak, at present numbering 102 cases. Most of the patients were school children.

Bequests to Charity.—The will of the late Marquis of Bute makes many charitable bequests, including £100,000 to be distributed among various Roman Catholic Institutions.

Treatment of Inebriety in Institutions.—A retreat at Buntingford requires 6 hours of hard labor from each inmate every day. This is outdoor work when the season permits it.

Medical Students Decrease in Number.—There is a distinct falling off in the numbers of students at the various colleges in England. The number diverted into the army is given as one cause of the decrease.

Monument to a Physician.—At Bedlington a monument to Dr. James Trotter was recently unveiled. The monument is in the form of a fountain, 21 feet high. Dr. Trotter had practised in the town for 30 years.

New Drainage Tube.—Dr. Steele, of Clifton, has designed a double channelled drainage tube. It can be used in any case, but is particularly useful in deep cavities where irrigation is used, one channel acting as an exit.

Glanders and Watering-Troughs.—It is stated that in the city of Belfast there has been no case of glanders since the troughs were discontinued in May last. They have been replaced by standpipes, each horseman furnishing his own bucket.

Medical Service in Scotland.—The question of medical service for the poor in Scotland is receiving much attention at present. An unsatisfactory condition exists as regards both the sick poor and the poor-law medical officers. The first class does not receive proper attention, and the second are underpaid. No advance in this line seems to have been made during the last 50 years.

Pathologic Laboratory at Bradford.—The municipal authorities have been petitioned to provide a public pathologic and bacteriologic laboratory. Suspected material is at present sent to Leeds. Cardiff is the only town in Great Britain which has its own health laboratory.

Sale of Patent Medicines in Great Britain.—The stamp duty paid on medicines during the year ended March 31, 1900, amounted to the sum of £288,827, being an increase over the preceding year of £22,423. There has been a steady increase in the net receipts since 1894 when the amount was £213,210, the lowest during the past 10 years.

Crime in England.—The annual report of the Commissioners of Prisons shows that practical results have been brought about by the Prisons Act of 1898. Improvement in the diet scale has not led to an increase in the number of criminals who would be attracted by better fare. Special efforts are made to bring moral and physical influence to bear on prisoners between 16 and 21 years of age. Insanity is steadily decreasing, which is gratifying when it is remembered that insanity in the country generally is increasing.

Lunacy in British Isles.—The report of the Commissioners in Lunacy for 1899 shows the total number of lunatics in England and Wales to be 106,611. Of these 58,075 were females and 48,536 males. The commissioners regret that alleged sufferers from insanity are still examined at police-courts instead of at their homes or the workhouse. They are also strongly in favor of the granting of pensions to the members of the staffs of lunatic asylums. The number of lunatics in Ireland in 1899 was 20,863. Many of the workhouses are said to be overcrowded and uncleanly.

Hospital Reform.—The report of the Medical Guild on Hospital Reform has been published. Among its recommendations are: That the investigation of the financial suitability of the applicants seeking relief at all medical charities should be the work of a central board, and that, in every case in which investigation is decided upon, it should be done thoroughly. That all trivial cases should be dismissed after the first attendance and that they, and all accidents (which should receive first aid), should, if not detained as in-patients, and if not fit objects of charity, receive no further treatment, but be referred to other sources. That the exaction of any payment whatsoever from patients should be entirely abolished.

CONTINENTAL EUROPE.

Dr. Leopold Javal, the eminent French ophthalmologist, recently lost his sight from the occurrence of glaucoma.

Dr. Yersin has returned to France after investigating the plague at Hongkong and Bombay. A report of the results obtained with the antiplague serum will soon be made.

Incubation Period in Malaria.—A case of malaria from Oporto, Portugal, is reported in the *Lancet*, which from certain circumstances places the incubation period at 18 days.

Lunacy in Italy.—The growth of insanity is causing alarm in Italy. There is a considerable increase of idiots, imbeciles, epileptics, etc., but alcoholic insanity maintains about the same proportion.

American Hospital in Paris.—Mrs. Leland Stanford has purchased a site in Paris for an American Hospital, upon which she will have the necessary buildings erected and give a sufficient endowment to maintain 60 beds and the staff needed.

Ulcer Cured by Röntgen Rays.—Stenbeck, of Stockholm, reports the cure of a rodent ulcer by daily exposure to the Röntgen rays. Each exposure lasted 10 to 15 minutes and was continued for several weeks. The hard edge was the most resistant.

The Society of Russian Surgeons was recently established in Moscow, membership being open to all practitioners in Russia upon the payment of 8 rubles yearly or 100 rubles at one time. The organizing secretary is Professor Diakanoff, of Moscow.

Preservation of Corpses.—An exhibit at the Paris Exposition showed the method of preserving bodies by means of formalin. One liter will preserve a body. It is claimed that a body treated in this way for 4 weeks is sterilized and will not decompose if kept in the open air for an indefinite time.

German Professor Injured.—Professor Rieder, of Bonn, fell from a hospital which is being constructed in Constantinople and sustained an injury of the spine and fracture of a foot. He is reorganizing the Turkish Medical Department.

Investigation of Cancer.—The Society of Thuringian Practitioners in Germany is to make a special investigation into the prevalence of cancer. The records of an insurance society show that where 1.43 per 1,000 persons died in 1875, 2.36 per 1,000 died in 1899.

Medical Certificates from Hospital Internes.—The Minister of Commerce in Paris has decided that a certificate given by a student *interne* is not a real certificate. A committee has been appointed to decide whether *internes* should have the right to practise in hospitals.

Gold Medal Founded.—The Swedish Medical Association in Stockholm has founded a gold Pasteur medal, to be awarded every tenth year to the investigator who has done the most to advance hygiene and bacteriology. Prof. Max Pettenkofer, of Munich, has received the first award of the medal.

The Plague.—The mortality in India still continues to rise, principally in Mysore State and Bombay. One new case has been reported in Sydney, Australia. The disease is also in Queensland, Brisbane, and Townsville. The other colonies have thus far remained free. A pronounced recrudescence of the disease has occurred at Mauritius, and the outlook is not satisfactory. Some of the large business houses in Australia are bringing suits for damages against the Government because of quarantine regulations. An officer in India offered to stop the plague in Bombay by burning all infected houses when the disease was somewhat limited. His offer was declined by the authorities, but a number of buildings were destroyed without fire in the hopes of getting at the nidus of the disease. The expedient was futile, resulting only in inconvenience to the people and authorities.

MISCELLANY.

Health of Boer Prisoners.—The Boer prisoners at St. Helena are healthy, very few of them being in the hospital at the present time.

Female Physicians in Asia.—Within the last 20 years the number of American and English female physicians in Asiatic countries has increased from 20 to 220.

Kashmir Mission Hospital and State Leper Hospital.—At the former 4,148 surgical operations were performed during 1899. At the latter there were 132 admissions and 4 deaths.

Beri-Beri.—H. M. S. *Sphinx*, which left Muscat September 13, and arrived at Bombay September 17, reports 5 cases of beri-beri on board. The vessel has been quarantined and disinfected.

Honor for Prof. Haffkine.—This director of the Government Plague Research Laboratory at Bombay has had conferred on him the Cameron Prize in therapeutics by the University of Edinburgh.

Herod's Method Employed.—Some students of the Patna Temple Medical School insulted one of the lady students of the school. As the real culprits could not be discovered, it is reported that the whole school was fined.

New Use of X-Rays.—A thief in Calcutta swallowed a diamond which medical treatment failed to dislodge. A skiagraph showed it to be lodged in the throat, where it is thought an artificial dilation had been produced for this purpose.

Chinese Treatment.—A cure for dyspepsia and flatulence is pinching the skin of the abdomen from the sternum to the pubis and around the sides. This is done violently enough at times to force blood from the skin. It is said to give immediate relief.

Cholera and Famine in India.—The numbers under famine relief are fast diminishing, but there are still 2½ millions on gratuitous relief. Cholera is prevalent in Kashmir, though it has decreased in Bombay. The British army is suffering but little from the disease at present.

New Ambulance.—An improved form of ambulance has been built for use in New Zealand. The space under the driver's seat is part of the interior and the bottom is only 16 inches from the ground. Two patients can be carried, one recumbent, the other in a semi-recumbent position.

Epilepsy from the Abuse of Coffee.—The *Indian Medical Record* cites a case, reported by Dr. Marburg, of a previously healthy woman of 41 who in 1893 began eating daily from 5 to 10 drams of roasted coffee beans. Tremor and spasm followed and in 1897 true epileptic convulsions began. In 1898 the coffee was denied her and the convulsions after a time entirely ceased.

Obituary.—DAVID YOUNG, of Rome, aged 61.—SIR HENRY WENTWORTH DYKE ACLAND, at Oxford, October 16, aged 85.—SAMUEL HENRY SWAYNE, at London, October 12.—RICHARD H. COWAN, at Wigan, October 6, aged 42.—MAX SCHAEFFER, of Bremen, aged 55.—ABRAHAM KUHN, of Strasburg, aged 62.—ALEX. TAREWICZ, of Cracow.—E. ALBERT, of Vienna.—RUDOLF ARNDT, of Greifswald, aged 55.—ALFRED SHEIREN, of Sydney, aged 56.—EDWARD H. O'DOHERTY, of Brisbane.—MISS DAGMAR BERNE, of Sydney.

The Plague.—The plague is again on the increase in India. In the Mysore State the deaths are still many in number and the disease is again developing in Bombay. In Calcutta the reports of the plague are practically the same as for several weeks, but the general mortality is increasing. The Bengal Plague Commission has made its recommendations and has been disbanded. A summary of the cases treated at the Alia Island hospital during the outbreak at Aden shows the Arabs to have combated the disease best. Mortality was least in cases under 20 years. A suspected case in London has demonstrated the efficiency of the precautions taken against the disease. No fresh cases have occurred in South Wales since the fatal case at Cardiff and that port has been given a clean bill of health. No fresh cases are reported from Glasgow.

Kashmir Mission Hospital.—In the returns for the Kashmir Mission Hospital, according to the *Medical Press*, there is a high proportion of cases of epithelioma of the thigh and of the abdominal wall. The exciting cause of this affection, as explained by the medical staff at this hospital, appears to be that the natives are in the habit of carrying about under their clothing a form of portable stove in the cold weather. The consequent burns and ensuing irritation result in growths which experience shows are quite capable of cure in the early stages. Unfortunately, however, advice is not generally sought until the trouble has reached the lymphatic glands, when, as might be expected, these cases assume a serious nature. The medical staff are congratulated on the very successful outcome of more than 300 operations for epithelioma in the course of the last few years, only one of which proved fatal.

Prof. Schenck Defends Himself.—In all the book-shop windows, writes a valued correspondent of the *JOURNAL*, G. H. H., is to be seen Prof. Schenck's little brochure, *Aus meinem Universitätsleben*, wherein he seeks to clear himself before the world of the charges by means of which his enemies ousted him from his position at Vienna. In the 69 pages he outlines the story of his 33 years of work in his laboratory at Vienna, how he had to live on a wretched pittance that did not permit him to appear in society even, to say nothing of tasting the other joys of life; how his work in biology had found recognition throughout the world, and how, since the year 1864, he had used every opportunity to investigate the laws governing the influencing of sex. He shows, further, that the newspaper announcement of his theory did not come from him, and was, besides, incorrect. Then he charges the University Court at Vienna of unfairness in that they refused to hear his witnesses, and in the second case gave him no announcement that his case was on and thus prevented him from putting in an answer. He shows how trumped up the charges against him were—being of actions of which at least half a dozen of the other members of the faculty were guilty. The cause of it all he lays at the feet of one or two colleagues, who out of hatred and envy and jealousy at his earnest labors and successes, have intrigued until they obtained the ear of the royal ministry and, *voilà*, he was out. He promises to bring out a larger and completer discussion of his theory in the near future.

The Latest Literature.

Berliner klinische Wochenschrift.

August 13, 1900 [37. Jahrg., No. 33.]

1. Neurofibroma in the Posterior Cranial Cavity. MONAKOW.
2. The Therapy of Impotentia Virilis. J. ZABLUDOWSKI.
3. The Determination of Blood-Pressure by the Tonometer of Gaertner. SCHÜLE.
4. Charcot-Leyden Crystals and Sperma-crystals. BENNO LEWY.
5. The Stomach Tube as a Peristaltic. OSWALD ZIEMSEN.

1.—v. Monakow calls attention to the small proportion of **brain-tumors** which are amenable to **surgical treatment**. v. Bergmann has stated that only tumors in the motor region and superficially seated are accessible for operative intervention. Tumors in the posterior fossa of the skull are not usually considered operable. Bergmann reports 12 tumors of the cerebellum which were operated upon, 5 of the patients dying during the operation from shock. In spite of these unfavorable results, successful cases have been reported, and Monakow is of the opinion that those tumors arising from the dura or the sheath of the eighth nerve, usually neurofibromas or fibrosarcomas, are not unfavorable for operative treatment. He has had an opportunity of examining carefully 3 cases at the necropsy. In one of these cases the patient was under his observation for several months and carefully studied, and a diagnosis was possible. In the other cases no definite clinical data was at hand. A careful report of the pathologic findings in these cases is given and the symptoms of such tumors are discussed at some length. [M.B.T.]

2.—The treatment employed is massage of the lumbosacral region, the perineum, the testes, and the prostate, together with active physical exercise, such as swimming, bicycle or horseback-riding, walking, etc. The details of the massage treatment should be read in the original. [D.R.]

3.—Schale in a series of experiments with Gaertner's **tonometer** found that **blood-pressure** was increased in arteriosclerosis, chronic nephritis, neurasthenia, and emotional states (melancholia). Cold baths and, according to certain authors, moderate physical exercise also increase the pressure. The **pressure is lowered** by anemic and cachectic conditions, by fever, during sleep, and in acute heart-failure. The tonometric investigations are at present not of great diagnostic value, but promise to be in time. [D.R.]

4.—Böttcher's **sperma-crystals** differ decidedly from Charcot-Leyden crystals, with which they have often been confounded. They belong to the monoclinic system and usually occur in long, prism like elements. Their edges are not straight, but curved; twin crystals are common. They may be obtained by drying spermatid fluid or allowing it to atand, when they may be found in the sediment. With Florence's reagent (a strong solution of iodine in potassium iodide) they take on a beautiful brown or violet color. Charcot-Leyden crystals are not octahedra but hexahedra and stain yellow with iodine. They occur under a great variety of conditions, particularly in leukemia, in asthmatic sputum, in the sputum of fibrinous bronchitis, sometimes in other sputum, in the intestine in cases of helminthiasis, in nasal polypi, etc. Their composition is not known, but there is some connection between them and eosinophile cells. [D.R.]

5.—The author has found that the daily use of the **stomach-tube with lavage** is a valuable stimulant to peristalsis, and an efficient means for curing **chronic constipation**. He introduces the tube in the morning on an empty stomach and pours from $\frac{1}{2}$ to 1 liter of Wiesbaden-Kochbrunnen water into the stomach, and immediately removes the fluid by depressing the tube. This procedure is repeated 15 or 20 times. He believes that the rapid filling and emptying the stomach acts as a sort of gymnastics to the musculature of that organ and that the effect spreads to the entire intestinal tract. Benefit has also been obtained in other diseases of the stomach,—in chronic dyspepsia, atony, distention, hyperacidity, neuroses, gastric ulcer with hemorrhage, and in diverticulums and other changes in the form of

the stomach. He has never had a bad result in gastric ulcer from the passing of the stomach-tube, but advises that novices abstain from the practice. [D.R.]

August 20, 1900. [37. Jahrg., No. 34.]

1. Concerning the Separation of Carbohydrates from Albumin. J. WOHLGEMUTH.
2. A Critical Examination of Milk Preparations. W. CASPARI.
3. The Effect of the Tesla Electric Current upon Metabolic Assimilation. A. LOEWY and TOBY COHN.
4. Therapeutic Experiments with Exchange Currents of Higher Frequency and Intensity (Tesla Electric Currents). TOBY COHN.

1.—Wohlgemuth has succeeded in separating from various albumins their **carbohydrate** constituent. The method employed consists in boiling the albumin in a beaker with a solution of hydrochloric acid of from 9 to 10% strength. He found a **hexose** constituent in vegetable albumin and also in lactalbumin. A nucleoprotein from the liver contained **apentose**. Casein, vitellin, and gelatin did not yield a carbohydrate. In some of the albumins the carbohydrate is combined with an amidoradicle. [D.R.]

2.—The author did not find tubercle-bacilli in the commercial milk product known as plasmon. [D.R.]

3 and 4.—**Tesla's currents** are rapidly alternating electric currents of high tension. They were discovered by Tesla and applied therapeutically by d'Arsonval. Their application to medicine is by some termed arsonvalization, but Cohn contends that the proper term is **teslaization**, in analogy with franklinization, galvanization, and faradization, named after the respective discoverers of the particular form of electricity, and not after the one who first employed it therapeutically. D'Arsonval claimed that Tesla's currents stimulate metabolism, but Loewy and Cohn were not able to corroborate this. The therapeutic use consists, as a rule, in placing the patient in a large cage (called solenoid) and passing the current through the cage, without the patient himself being directly connected with the electrodes. There is also a method of direct induction into the patient through the electrodes. The treatment was tried on 76 patients with various functional and organic nervous diseases, and in disturbances in metabolism and joint and skin affections. In no case was there any objective change discoverable. There was apparently no influence on the blood-pressure or metabolism. Subjective improvement was noticed in a large number of cases; sleep, particularly, seemed to be favorably influenced. This subjective improvement is ascribed to the effect of suggestion. [D.R.]

Wiener klinische Wochenschrift.

August 16, 1900. [13. Jahrg., No. 33.]

1. The Warning from Pulsating Ophthalmus. ROMULAD KESCHMANN.
2. Concerning Echinococcus Tumors. D. KOKORIS.

1.—A case of **pulsating exophthalmus** is reported in a boy 14 years old. The right eye was pushed forward and downward. The eyeball was about 3 mm. more prominent than the left and pulsated synchronously with the radial artery. The pulsation was stronger on deep expiration, weaker after compression of the right carotid, though it did not cease entirely. By bending the head forward it was not influenced. No bruit was noticed on auscultation. The tarso-orbital fold was obliterated, the upper lid was much thickened and the conjunctiva injected. The palpebral slit was opened only at the middle; the lower lid was also moderately thickened. In addition to the condition of the eye there was partial thickening of the frontal and temporal bones, flattening of the frontal bone, shortening of the right side of the maxilla, paresis of the right internal pterygoid muscle, atrophy of the temporal and masseter muscle, and atrophy and hyperesthesia of the right half of the tongue. There was a high degree of myopia in the right eye, but entire absence of changes in the retinal field. A diagnosis was made of cavernous angioma in the vicinity of the optic foramen and the superior orbital fissure, and lesion of the second branch of the trigeminus through bony pressure or a fissure in the wall of the foramen rotundum. Ligation of

the common carotid was not performed because of the objection of the father, but an operation was undertaken for the relief of the ptosis and ectropion, which was successful. Because of the great danger to the eye immediate treatment is advised for all these cases. Digital compression of the common carotid may be first tried, and if unsuccessful the carotid should be ligated. Pulsating orbital angiomas may be successfully treated by galvanopuncture in some cases if they can be reached. [M.B.T.]

2.—Kokoris reports a case of an *echinococcus* cyst in a woman 26 years of age. The tumor was located on the right side of the neck. It was about the size of a fist, rounded and with a smooth surface. It fluctuated clearly. All the muscles innervated by the right brachial plexus were very atrophic. The right shoulder was hyperesthetic and the right pupil was narrower than the left. An incision was made along the posterior border of the sternomastoid muscle. The cyst was opened and its contents evacuated. With the finger in the cavity the fourth, fifth, sixth and seventh cervical vertebrae could be felt. The entire cyst-wall was removed and the cavity packed with iodoform gauze strips. Perfect recovery by granulation eventually resulted. In a second case a woman of 25 years of age had multiple echinococcus cysts in the peritoneal cavity. The abdomen was uniformly distended and had an elastic firm feel at many points. Tumors with a smooth surface slightly movable could be made out. Exploratory puncture was made and a clear fluid containing characteristic hooklets was evacuated. Celiotomy was then performed and on opening the abdomen a cyst the size of an egg presented. A tumor was adherent by a broad base to the omentum. After ligation it was severed from its attachment with a thermocautery. There were so many and so firm peritoneal adhesions that it was decided not expedient to try to do more. A second, third, fourth, and fifth operation were undertaken. From 7 to 26 cysts were removed at each operation. After the last operation peritonitis developed which resulted fatally. [M.B.T.]

1. Conclusion of Report of International Medical Congress of Paris.
2. A Case of Fecal Tumor. W. POTEN.
3. A New Knife for Puncturing the Portio. HERMANN BIERMER.

2.—Poten reports a case of fecal tumor mistaken for a hard myoma; but the change of its position following a free use of klysters preparatory to operating for the myoma, revealed its true character and it was treated accordingly. [W.K.]

3.—Biermer describes a new instrument adapted to puncturing the portio. [W.K.]

August 25. [No. 34.]

1. The Effect of Formol in Uterine Hemorrhage. GERSTENBERG.

1.—Gerstenberg, having seen the evils resulting from the use of pyroxylic acid to control hemorrhage, determined to test the value of formol for the same purpose; and in his experience in a series of 10 cases the results were entirely favorable. He admits that gynecologic hygiene played its part in the improvement of these patients, but claims that in the majority the favorable influence of the use of concentrated formol was unquestionable. He recommends it especially for climacteric hemorrhages. In 2 cases of postabruptive hemorrhagic endometritis, 3 applications of formol were made with entirely satisfactory effect. In hemorrhage from inflammation of the adnexa he regards the use of formol as an important adjunct where operation is refused, and also thinks it exercises a good influence on the badly contracted uterus in a case of postpartum subinvolution. Not one of the patients under his care has received any injury from it and 8 of them have already returned to their usual activities. He has observed no appearance of stenosis. [W.K.]

1. A Case of Hypertrophy of the Mammary Gland. CARL DONATI.
2. A Case of Perforation of the Fetal Head *intra partum* with Recovery of the Child. L. PERNICE.
3. An Obstetric Satchel of the Year 1889. KREVE.

1.—Donati adds 1 more to the short list of reported cases of diffuse hypertrophy of the mammary gland. His patient, aged 19, had had a severe attack of diphtheria in her fifth year, and some chlorosis in her fifteenth year, and had acute nephritis when first seen. She came to the hospital in the eighth month of her first pregnancy, and it was decided to empty the uterus because of the severe nephritis, from which she was suffering. She was successfully delivered of a dead fetus. The unusual feature in this case was the enormous size of the breasts. There was no evidence of cyst or solid tumor; both glands were about evenly developed, were symmetric and firmly elastic. The distance from the papilla to the middle of the third rib (beginning point of the breast) was in the right breast 28 and in the left 27 cm. The distance between the 2 papillas was 27 cm. The greatest circumference was the same in both breasts, 46 cm. The nipples were small, about the size of a hazelnut. No diminution in the size was noticed during the 5 weeks after her confinement, in which she remained under observation. At that time she removed, and further control of her case was impossible. [W.K.]

2.—Pernice reports the unique case of a child whose skull was perforated *intra partum* under the mistaken diagnosis that the case was one of hydrocephalus. He first saw the child when it was 1½ years old. It was entirely normal in every way except that at the middle line of the suture joining the parietal and occipital bones there was a small tumor half the size of a lapwing's egg, which only at the base was covered with hair. At the time of the confinement the mother had very slight labor-pains, and after 7 hours the obstetrician, believing that the lack of progress was due to a hydrocephalic head, operated. The birth followed immediately thereafter and the severe bleeding from the wound of the head was soon controlled. Three weeks after birth 2 small swellings were apparent and these were incised. One contained blood and water, the other thick pus and blood. Immediately after birth paralysis appeared. The child is not able to move the left arm or the left leg. Otherwise its development, both in mind and body, is normal. Pernice was desirous of doing a plastic operation for the relief of the child's condition, but the consent of the parents could not be obtained. [W.K.]

3.—Krevet recommends very highly an obstetric satchel made according to his orders by a firm in Breslau, which he has used for 10 years. It is very compact and contains a disinfecting tray together with all the medicaments and instruments likely to be needed in any obstetric case. [W.K.]

September 8, 1900. [No. 36.]

1. Instrument for Intravesical Therapy in Women. SIGMUND MIRABEAU.
2. A New Vaginal and Hot Water Irrigator. CH. HASSE.

1.—Mirabeau describes an instrument of his own invention adapted to the removal of foreign bodies from the female bladder, or to the application of therapeutic treatment internally. It consists of a handle and a carrying-tube into which a cystoscope can be adjusted and thus easily introduced into the bladder; or by it may be introduced any one of the 5 instruments which he has fitted to it, namely, small forceps, little knife, curet, scissors, and stone-carrier. It is simple in construction and easily managed. When by means of the cystoscope the foreign body or the diseased portion of the bladder has been located, after the removal of the cystoscope, whatever other instrument is needed can be adjusted to the handle and the proper treatment intelligently conducted. [W.K.]

2.—Hasse has invented a new instrument for vaginal irrigation with hot water, which consists of a pear shaped glass balloon, through which passes a double glass tube. One advantage of this instrument is that the sensitive parts are protected from injury by the double layer of air and glass, which forms a poor conductor of heat. [W.K.]

LOCAL AND REGIONAL ANESTHESIA WITH COCAIN AND OTHER ANALGESIC DRUGS, INCLUDING THE SUBARACHNOID METHOD, AS APPLIED IN GENERAL SURGICAL PRACTICE.

By RUDOLPH MATAS, M.D.,

of New Orleans.

Professor of Surgery Medical Department, Tulane University of Louisiana.

Is a contribution entitled "The Growing Importance and Value of Local and Regional Anesthesia in Minor and Major Surgery," which was presented to the Louisiana State Medical Society at its last meeting in April, 1900, I had occasion to express my conviction that all the dangers of general anesthesia with the classical anesthetics chloroform and ether, whether alone or in combination with other agents, are not sufficiently appreciated and that the present indications for their use are far in excess of the actual demands of practice. I also ventured to emphasize my conviction "that an unfounded and scarcely justifiable skepticism still prevails among many excellent, skillful and otherwise progressive surgeons, who, having neither the inclination nor the patience needed to acquire the most advanced and effective methods of local and regional anesthesia, or who, still confusing the imperfect and dangerous methods of the past with the safe and efficient methods of the present, still doubt and cling to general narcosis as the only means of abolishing pain in their operations. Others again, who while apparently recognizing the practical utility of local anesthesia will not hesitate to open an abscess, remove an ingrown toe nail or even amputate a finger with cocain,—will smile with incredulity if in a case requiring the amputation of an arm or of a leg, some one suggests the propriety of using cocain or eucain as the anesthetic."

At the time these remarks were written I was perfectly cognizant of the method of spinal cocainization and had already applied it in several cases¹ and devoted considerable attention to its technic and application in the same contribution. In this I welcomed it as an additional and most valuable resource in those conditions in which general anesthesia was contraindicated or in which the more restricted regional methods were inapplicable.

This method I will again consider in this publication, but my main object on this occasion is to call attention to older methods; or, more correctly, to the more advanced and systematic applications of principles and methods which have been recognized by the profession for some time past, but have not been sufficiently utilized by surgeons in many grave and major conditions in which a general anesthetic would have to be resorted to with far greater risk and positive danger. While these methods are certainly not so brilliant in their immediate results, nor so simple in their technic, and certainly demand much more patience and a longer anatomic as well as surgical training than the spinal subarachnoid procedure, they are just as effective, much safer, and are

susceptible of more general application and to a larger class of patients who call upon the surgeon for relief.

At this moment, when in consequence of the great impetus given to the spinal subarachnoid method by the brilliant demonstrations of Tuffier before the crowded audiences that came from all parts of the world to attend the Thirteenth International Medical Congress, held in Paris during the past summer—a wave of curiosity blended with enthusiasm is sweeping over the entire country, and almost every surgeon is impatient to try (and if he has tried, to report) the "New Method," it is not likely that communications bearing upon less brilliant methods, which require time and much patience to acquire, will be received with special favor. The comparatively slow and more limited methods of infiltration and neuroregional anesthesia must now appear to disadvantage, as not in harmony with the spirit of the moment, and may even savor of the antiquated or retrogressive. But it should be borne in mind that, after all, the method of spinal cocainization is only an extended though specialized form of neuro-regional anesthesia, and that as such it has its distinct anatomic limitations, and that while the area which it embraces represents the most fertile surgical territory in the body, there are still other numerous regions in which it is totally ineffective or inapplicable and in which the resources of local and regional anesthesia still find frequent and most useful application.

It is therefore not in a spirit of rivalry and antagonism that I venture to call attention to the methods herein described; on the contrary, my aim is to utilize all available methods that will suppress pain, provided these may be made safe and effective.

In this paper I have simply alluded to the dangers of the general anesthetics. The simple fact that so many experienced surgeons the world over have accepted the new and yet unfathomed method of spinal cocainization as a substitute for the general anesthetics is the best proof of dissatisfaction in existing conditions and is a practical admission of the fact that there is still much room for improvement. The danger now lies in the other direction. In our efforts to escape from the dangers of Charybdis we are running into the perils of Scylla; and it is not unlikely we shall witness a repetition of the same errors which so disastrously characterized the early history of cocain anesthesia and which threatened for a time to bar it out of the field of general surgical practice. Cocain was then discredited in consequence of the frequent and alarming fatalities which resulted from overdosing and from the imperfections of the technic; a condition of things which may again be repeated with still greater reason in consequence of the indiscriminate and reckless application of the method in injudicious and unskilled hands. The wave of enthusiasm which is at present sweeping over this country will undoubtedly furnish the necessary data needed to form a true estimate of the possibilities and the limitations of the method. But at what cost we cannot tell; that we shall soon be able to take an inventory at its just valuation cannot be doubted. In the meantime the general anesthetics will remain, as they must ever, with us, if not in the present form in some other, and in spite of their dangers and disadvantages, because unconsciousness in surgical operations is still a desideratum in many interventions, if only to abolish the *psychic* pain which, at times, cannot be even palliated by the most complete analgesia.

Therefore, while we are seeking by every means sug-

¹ My first application of the spinal subarachnoid method was made in November 10, 1899. I had already called attention to the American origin of the method in an article on the "Progress of Surgery in the United States," *Journal American Medical Association*, June 3, 1899, p. 1212, at a time when the original observations of Dr. J. Leonard Corning on this subject had been apparently forgotten and all the credit of the suggestion and application of this method were exclusively attributed to Professor Bier, of Kiel.

gested by reason, ingenuity, and experience to minimize the dangers of these necessary evils—the general anesthetics—let us continue to develop and perfect the various methods of local and regional anesthesia which permit us, in suitable conditions, to obtain the same results without peril to the organism or injury to the part involved.

* * * * *

THE EVOLUTION OF THE MODERN TECHNIC OF LOCAL AND REGIONAL ANESTHESIA IN SURGICAL PRACTICE.

This may be briefly epitomized in a simple statement of the various discoveries which have exercised the most potent influence in widening and perfecting the methods of local and regional anesthesia.

To the student of American surgical history it will be a source of pleasure to recall the fact that probably the first clinical demonstration of the value of cocain when used by the subcutaneous method for purposes of surgical anesthesia were made by American investigators. Beginning with the earlier experiences of Hepburn (November 15, 1884), which followed closely upon Karl Koller's epoch-making announcement of the true anesthetic properties of cocain at Heidelberg in September, 1884, and continuing with the clinical experiments of Hall and Halsted (December 6, 1884), the physiological experiments of H. W. Biggs (1885), and culminating in the remarkably original and brilliant series of papers contributed by J. Leonard Corning (1885–1894) it is gratifying to note that the essential and fundamental principles upon which rests the most effective technic in cocain-anesthesia had been foreshadowed and in some particulars completely elaborated by these early pioneer efforts of American surgeons and investigators.

I.

The discovery that anesthesia of the skin or derm proper by *intra-dermal* infiltration with cocain or similar analgesic agents, as distinguished from the hypodermal method, is the key to success in local anesthesia—*i. e.*, the anesthesia of the field of operation. This fundamental fact seems to have suggested itself at the same time to several observers, but the names of W. S. Halsted (1884), J. L. Corning (1885), Reclus and Ich. Wall (1886), and Schleich (1890), are the first and most prominent that occur in the literature of the subject, though Halsted was the first to insist upon the importance of the intra-dermal method and to demonstrate by a large clinical experience its great practical importance.

II.

The discovery that the tissues are sensitive to the anesthetic action of extremely dilute solutions of cocain and other analgesics (1 to 20,000 parts, Schleich, Heinze), and that these can be used effectively in exceedingly weak and positively nontoxic doses.

Corning showed the effectiveness of solutions (warm) of $\frac{1}{3}$ of 1% cocain in 1885. Reclus rendered great service by his forcible and constant pleading in favor of solutions not stronger than 1%, which he used as early as 1886; but to Schleich belongs the great credit of reducing the strength of the surgical solutions to $\frac{1}{5}$, $\frac{1}{10}$, and $\frac{1}{100}$ of 1%. His experiments began in 1888, but their value was not fully recognized until the publication of his great work, "Schmerzlose Operationen," in 1894.

III.

The discovery by Schleich (1888), that the thorough

edematization of the tissues with physiologic *isotonic* solutions of sodium chlorid (.2%, Schleich; .8%, Heinze) at a low temperature is in itself, as a physical process, an anesthetic agent. The clinical evidence on this point began with the observations of Potain (1869), Dieulafoy (1870), Lebroue (1870), and with Liebreich's researches on the anesthetic properties of pure water; Halsted independently called attention to the same property of distilled water when infiltrated into the derm, and also called attention to the efficacy of very dilute solutions of cocain as early as 1885.² While saline infiltration is not to be ranked as a surgically practical anesthetic, it is a most powerful adjuvant to local anesthesia, by increasing the effectiveness of extremely dilute solutions of cocain in many ways that will be referred to later.

IV.

The very important discovery made by Dr. J. Leonard Corning, of New York (1885), to the effect that the action of cocain can be indefinitely prolonged as long as the circulation of the anesthetized area is arrested by elastic constriction or other mechanical devices. This is Corning's first great discovery, undoubtedly the most important contribution made in the early period of the surgical history of cocain, as it exercised a most beneficial influence in encouraging the practice of local anesthesia by improving the results and diminishing its dangers. The value of circulatory stasis in prolonging and intensifying the action of local anesthesia had been fully recognized by Chandelux, of Lyons, who, basing himself upon the previous studies of Letamendi and Cardenal, of Barcelona, had already, in 1885, applied the elastic constrictor to intensify the action of the ether spray. He made no allusion to cocain, however, in his paper. The advantages of the constrictor in cocain operations also apparently occurred independently to Mayo Robson, of Leeds, in 1886. Kummer, of Geneva, especially insisted, in 1889, upon the value of stasis and constriction to diminish the dangers of toxic absorption. Notwithstanding the fact that he duly credited Corning with the suggestion, many French and German writers still persist in referring to the application of the constrictor as "Kummer's method" of local anesthesia.

V.

The discovery that the infiltration of the sectional area of a nerve-trunk, in any part of its course, with cocain or similar analgesics, is followed by a sensory paralysis of its entire peripheral distribution. The effect of cocain when applied in contact with a nerve is to "block" (Franck) the way to all apparent or sensory impressions up to the point where the injection or "blockade" exists. The effect of the drug is not limited to the sensory fibers, as at one time taught, but it paralyzes all nerves whether motor or sensory, only that the anesthesia is much more promptly manifested than the motor paralysis. Its action upon nerve-trunks is so positive that F. Franck proposed, in 1892, that cocain be substituted for the knife in experimenting on animals and spoke of its action "as physiological section" of nerve, differing from section with the knife solely in the fact that the effect was transitory and never injured the integrity of the nerve. The anesthetic action is of variable duration according to the dose of the drug applied,

² See his "Practical Comments on the Use and Abuse of Cocain; Suggested by its Universally Successful Employment in more than One Thousand Minor Surgical Operations." *New York Medical Journal*, September 19, 1885.

the duration of the application, and the size of the nerve. The paralytic action of cocain is continued indefinitely and is intensified by arresting the circulation in the injected and anesthetized nerve-tract. When absorption is not interfered with, the function of the nerve returns gradually and completely, leaving it without a trace, functionally or structurally, of its former paralyzed condition.

The local action of cocain on nerve-fibers was studied experimentally by physiologists long before the possible value of this knowledge in surgical practice had been thought of (Van Anrep, 1880; H. W. Biggs, 1884; *et al.*)

The discovery of the paralyzing action of cocain on nerve-trunks is the present foundation of the *neuro-regional*, as distinguished from the purely *local*, methods of anesthesia. It is interesting to note that the observations of the clinicians largely anticipated the future demonstrations of the physiologists, and were conducted independently of all inspiration from the laboratory. Thus we find that the first demonstration of the surgical value of the principle of neural cocainization is due to Hall and Halsted, who experimented with the drug upon themselves and upon others in 1884. Hall anesthetized his infraorbital to anesthetize teeth, and Halsted injected the inferior dental at the spine of Spix with 9 minims of a 4% solution, thus obtaining a complete anesthesia of the gums, teeth, etc. (Vide *New York Medical Journal*, December 6, 1884.)

The action of cocain on nerve-trunks was also appreciated by Dr. Leonard Corning in 1885, but he did not utilize the neural method as as a distinct surgical procedure. The same facts were observed by Barranhea, of Santiago, Chili, in 1885, and he obtained anesthesia of the teeth by injecting the inferior dental nerve as it enters the inferior dental canal at the spine of Spix. These early but indisputable applications of the neuro-regional method in America had long antedated the methods of German operators, and had in fact been forgotten until it was again introduced to us as the method of Oberst, of Halle (1886), as it is known in Germany, and of Krogus of Helsinfors (1894), as it is still designated by Reclus.

It may be safely stated that up to 1897 the principle of nerve cocainization was utilized only in an indirect manner and even at this moment there are few if any of the more advanced regional surgeons in Germany who apply it except by subcutaneous or submucous injection, *i. e.* the paraneural method. The direct, *open* injection of nerve-trunks with cocain anesthesia was first practised (as far as I have been able to ascertain) for surgical purposes, by Dr. George W. Crile, of Cleveland, Ohio, who amputated a leg painlessly after injecting the sciatic and anterior crural nerves on May 18, 1897, and by the writer, without any knowledge of Dr. Crile's operation, on January 18, 1898, in a partial amputation of a hand, after a preliminary direct cocainization of the ulnar, median, and musculospiral nerves at the bend of the elbow. The same principle has been admirably utilized by Dr. Cushing and others in Dr. Halsted's clinic (Johns Hopkins Hospital) about the same time (1897) for anesthetizing the inguinal region in the radical cure of hernia.

VI.

The discovery of a number of local analgesic drugs of which eucain B. (Silex, 1897), and nirvanin (Einhorn and Heinze, 1898), alone deserve to be classed as the succe-

danea of cocain. Because of lesser toxicity and their capacity to stand boiling without decomposition, and for other reasons, they may be utilized with advantage alone, or in conjunction with cocain; in this way, while not superseding cocain, they have undoubtedly contributed to widen and diffuse the practice of local anesthesia.

VII.

The greater appreciation in recent years of the physiological fact that all the tissues and organs of the body, with the notable exception of the papillary layer of the skin and the nerves, are, in normal conditions, practically devoid of sensibility; and that if the sensation of the derm, and of the nerves that supply a given region, is subdued by an artificial anesthetic, the sensibility of the tissues can be practically disregarded from the operative point of view. On the other hand, the importance of psychic pain in the course of operations is not to be underestimated; and as this cannot be controlled by purely local anesthetic agencies it remains a serious obstacle which in major surgery frequently compels a recourse to general or cerebral anesthetics in spite of the total abolition of sensation in the field of operation. The evidence on this point can be traced to numerous and even ancient sources, but its great significance in the practice of local anesthesia has been most forcibly presented by Dr. O. Bloch, of Copenhagen. (*Bibliotek for Læger*, Copenhagen, 1898; *Revue de Chirurgie*, Paris, January 10, 1900; see also H. Lillenthal, *Annals of Surgery*, vol. xxvii, 1898.)

VIII.

The discovery that the central analgesic effects of morphin on the cortex and physical centers greatly assist in preparing the mental attitude of the patient for the action of local anesthetics, has materially contributed to the success of local and regional anesthesia. This suggestion independently occurred to many operators simultaneously, but Ceci, of Genoa, has, since 1897, insisted upon the systematic use of morphia as a preliminary to local anesthesia; and the value of the suggestion has been recognized in almost all clinics where cocain is most frequently resorted to.

IX.

The discovery that by utilizing the anesthetic properties of cocain and other local anesthetics (including ethyl chlorid, Bloch) with morphin, a preliminary stage of diminished sensibility is produced which is also most favorable to the action of general anesthesia so that an important group of major operations which cannot be undertaken with local anesthesia alone, and in which the condition of the patient contraindicates chloroform or ether, can be painlessly performed with the aid of a very superficial, intermittent and *purely cortical* anesthesia ("morphin-cocain-chloroform anesthesia"). In the method the essential point is also to subdue the sensibility of the skin as a preliminary; after this is accomplished very little chloroform will be required to complete the operative work in the deeper tissues. No saturation with chloroform as a rule will be required and in this way the dangerous effects of the drug will be avoided or will be reduced to a remarkably safe minimum. (See O. Bloch, *l. c.*, Schleich, *l. c.*, and H. Cushing, *Annals of Surgery*, January, 1900.)

X.

The discovery that the cerebrospinal fluid can be used as a diluent medium for cocain or other analgesic drugs of the same types and that the posterior roots of the spinal nerves are extremely sensitive to the anesthetic action of these drugs when introduced into the spinal subarachnoid space, thus providing another and most effective mode of obtaining complete insensibility of the lower extremities, and other parts supplied by the spinal nerves. This method, which we owe to the inventive genius of Dr. J. Leonard Corning, of New York, was foreshadowed by him as early as 1885 ("Local Anesthesia," D. Appleton & Co., New York, 1886), more fully elaborated in his article on "Further Contributions on Local Medication of the Spinal Cord," *Medical Record*, New York, March 17, 1888, and completed as a demonstration in 1894, "Irrigation of the Cauda Equina with Medicinal Fluids," in his book on "Pain" (J. B. Lippincott Company, 1894). Corning's studies and observations had been forgotten when the possibility of utilizing the subarachnoid space and the cerebrospinal fluid as a comparatively easy avenue to the cerebrospinal centers for direct diagnostic exploration and medication, became the subject of investigation in Europe.

The facility with which the contents of the subarachnoid space could be reached by lumbar puncture for diagnostic and therapeutic purposes was first made apparent by Quinke in 1891 ("Die Lumbalpunktur des Hydrocephalus," *Berliner klinische Wochenschrift* 1891), and he was followed by a number of investigators who contributed to the perfection of the technic of lumbar puncture. Then came the clinical experience of Sicard, of Paris, Jaboulay, of Lyons, and Jacob, of Berlin, all in 1898, in medicating the cerebrospinal fluid with antitetanic serum for tetanus and other spastic conditions; but it was not until April, 1899, that the first use of cocain, introduced by lumbar puncture, for surgical purposes was made known to the profession by Prof. Bier, of Kiel (*Deutsche Zeitschrift für Chirurgie*), in which he completely demonstrated the success of this method. About the same time, Sicard made a most valuable experimental study of the action of cocain on the cerebrospinal axis, including the brain (*Compt. Rendus Société de Biologie*, May 26, 1899), which, together with the contemporaneous studies of Jaboulay and Jacob in the same direction, completes the experimental evidence on the subject, though a great deal of important evidence on the action of cocain on the nerve-centers had been previously obtained by the earlier physiological investigations of Mosso, Aducco, Baldi, Odier, Franck, and many others.

It was the first clinical observation of Bier, however, that gave the subarachnoid method its present surgical importance and has opened the new field which is being rapidly crowded with the observations of a host of surgeons whose contributions are now creating a new chapter in the bibliography of anesthesia. The Corning-Bier method, as we may properly designate anesthesia obtained by the spinal subarachnoid route, marks the culminating point in the history of cocain technic and of regional anesthesia. Its technic, indications, and results will be more fully considered in another section.

* * * * *

As the result of the practical applications of the principles embodied in these ten discoveries or generalizations, the technic of local and regional anesthesia has been gradually evolved into a method, or a variety of

methods, which for efficiency and safety far outstrips the most sanguine expectations of the early advocates of cocain anesthesia. Not only all the exigencies of minor surgery are met with success by the new methods, but they are applicable with still greater force in a constantly increasing number of grave, critical and major conditions which, a few years ago, would have been regarded as absolutely impracticable without the aid of general anesthetics.

* * * * *

Before proceeding to consider the field of application of the new technic and the advantages that can be gained by its more frequent and systematic application in general surgical practice, let us first define and classify these methods in order that their indications and limitations may be the better understood.

CLASSIFICATION OF THE METHODS OF LOCAL AND REGIONAL ANESTHESIA IN WHICH COCAIN AND OTHER ALLIED ANALGESIC DRUGS ARE UTILIZED AS THE ACTIVE AGENTS.

It should be first clearly understood that the artificial anesthesia of any given tissue or organ of the body is entirely dependent for its production upon the suppression of sensation of all sensorial (irritant) impressions made upon that region through the agency of the nervous system. This suppression can be affected by: (1) paralyzing the peripheral nerve-endings or terminal organs of sensation, as in the papillary layer of the skin; or (2) by "blocking" or obstructing the path of all sensorial impressions in the nerve-trunks, including (3) the sensory roots in the spinal cord that connect the field of operation with the sensorium; or (3) by anesthetizing the sensory centers in the cerebral cortex itself.³ This last route is only an experimental possibility and is not available as a surgical method. In regional surgery with local analgesic drugs the effects (1), (2) and (3) are utilized and may be obtained by the following methods:

1. *Local Infiltration Method.*—By infiltration we mean the production of an artificial edema of the tissues with the object of diminishing or suppressing their sensibility. Plain or distilled water when injected in sufficient quantity to edematize the papillary layer of the derm and subjacent tissues will suffice to produce a transient but painful anesthesia of the edematized area. This is "the anesthesia dolorosa" of Liebreich. The pain is caused by imbibitory swelling of the cells. Solutions of the same specific gravity and the same freezing point as the normal tissue fluids are the only ones which can be employed without causing pain from osmotic disturbances and are called *isotonic* solutions (De Vries). More concentrated solutions will draw water from the tissues and cause pain; weaker solutions cause the tissues to swell and are similar in their effects; the nearer they approach pure water the greater the pain. An indifferent fluid iso-osmotic with the blood produces neither pain nor anesthesia.

A warm, osmotically and chemically indifferent fluid with a freezing point of about 0.55° C, is the medium which, when injected, produces no physical effects *per se* and leaves the specific action of the analgesic drug (cocain, eucain, etc.), to act alone. According to Heinze and Braun, such a medium is a 0.9% watery solution of common salt at the body temperature. Heinze (1898)

³ See experimental evidence bearing on intracranial cocainization furnished by Charpentier, Tumass, Bianchi et Giorgetti, Carvalho, Aducco, Mosso, and F. Frank from the physiological point of view; and of Jaboulay and Sicard from the therapeutic standpoint.

has also determined that within certain limits, from 0.6% to 2%, the osmotic action of sodium-chlorid solutions is so slight that the injection is entirely painless. A knowledge of these facts is of practical interest because by the use of isotonic or physiologic salt-solutions the tissues are not injured and they recover more promptly and without irritation from the effects of analgesic agents. Hence the use of salt in all local anesthetic solutions. Schleich, who is the father of the infiltration method, was the first to call attention to the value of salt in preventing the pain produced by plain water infiltration, and while many of his conclusions have been more or less contradicted by the experimental studies of Custer, Heinze and Braun, the fact remains that his first appreciation of the remarkable sensitiveness of the tissues to such weak dilutions of cocaine as 1 in 20,000 revolutionized the technic of local anesthesia and gave new impetus to this mode of practice. According to Schleich the edematization of the tissues with a salt-solution (2%) at a lower temperature than the body heat is the essential condition required for the production of local anesthesia. The small quantity of the analgesic drug that he adds to his solutions ($\frac{1}{100}$, $\frac{1}{1000}$, of 1% cocaine) is simply intended, he claims, to suppress the abnormal hyperesthesia of pathologic tissues. When dealing with normal tissues he believes that a plain .2% salt-solution is sufficient to anesthetize, provided the tissues are thoroughly edematized.

The *modus operandi* of the simple infiltration method, as he admits, does not depend solely upon the injection of an isotonic salt-solution; there are other factors which enter more powerfully into the causation of the anesthesia; these are: (1) The ischemia of the tissues and partial stasis caused by the great pressure exercised by the injected fluid on the capillaries and bloodvessels; (2) the compression of the terminal nerve elements themselves from the same cause; (3) the lower temperature of the infiltrated area caused by using cold solutions, or by cooling these after their injection into the parts. These purely *physical* conditions are undoubtedly of great importance in favoring and intensifying the action of the analgesic drug, and upon the thoroughness with which they are brought to play largely depends the success of the infiltration method as it is practised by Schleich. That Schleich has underestimated the importance of the paralyzing effects of the cocaine which enters into the composition of the solution cannot be doubted. Heinze and Braun contend, as a result of numerous experiments, that Schleich's solutions owe their entire analgesic effect to the cocaine they contain, and my personal experience has convinced me that if the cocaine were excluded from them they would cease to be of value as practical surgical anesthetics. On the other hand, we must recognize that without the process of edematization the weak solutions of cocaine which Schleich has taught us to use so effectively would become practically worthless.

From the preceding discussion it is evident that there are two efficient factors concerned in the production of infiltration anesthesia, which must be clearly differentiated from one another. One is the *physical* effect of the infiltration from pressure, differences of temperature, etc. (Schleich); the other, is the *chemical* action of the drug employed (cocaine, eucaine, etc.) to paralyze the sensitive structures. According to the preponderance of the physical or the chemical factors, we may classify the practice of local anesthesia by infiltration into two dis-

ting methods: First, Schleich's method, with a very weak cocaine solution, which depends upon the infiltration itself as the effective agent, and lays the greatest possible stress upon its physical action; and, second, the method of Corning, Reclus, and the earlier German anesthetizers (Wölfle, Landerer, etc.), in which the tissues are injected, layer by layer, with stronger solutions (1 to 4% cocaine), and which depends for its efficiency almost exclusively upon the diffusion of the chemical analgesics dissolved in the solutions.

Since the introduction of eucaine B. and nirvanin, which can be used in relatively concentrated solutions without fear of toxic effects, and since the neuro-regional method has been perfected so that a maximum effect can be obtained with a safe minimum expenditure of the drug, a decided tendency is noticeable at the present time to depend more upon the action of the analgesic drugs than upon the physical or mechanical effects of the infiltration process itself.

The preference given in the selection of these methods will be determined by various conditions, which will be more readily appreciated in connection with the topographical application of the technic in the various regions of the body. A correct judgment on this point largely depends upon the individual experience of the operator with the various methods, but the best results will be obtained by the operator who is thoroughly familiar with *all* the methods, and who knows how to combine them in the most effective manner to meet the requirements of each individual case. In a very general way Schleich's method of infiltration is indicated in all operations in which the circulation cannot be controlled and in which the major part of the infiltrating solution must be allowed to remain in the tissues. On the other hand, it must be remembered that some of its most brilliant effects have been obtained in the major surgery of the extremities, when elastic constriction sufficient to arrest the circulation and absorption remarkably intensifies its effect and prolongs its duration. (Schleich himself does not depend upon the elastic band.) One of the chief reasons for the frequent failure of the infiltration method and the dissatisfaction that is expressed by many who condemn it as inadequate, is due to the imperfect application of the two fundamental rules—the first, which applies as well to all methods of anesthesia, is that the derm proper, and especially its papillary layer, must be first edematized by *intracuticular* infiltration before beginning the edematization of the deeper planes, the same rule applying to mucous surfaces. This is a *sine qua non* in local anesthesia which cannot be repeated too often. The second rule is, that in using Schleich's weak solutions, especially Nos. 2 and 3, the intensity of the anesthesia as well as its duration will be directly proportional to the thoroughness with which the tissues are edematized. The field of operation in strictly *local* infiltration must be literally packed and made *tense* with the injected fluid, so that all the elements of the tissues may be brought in contact with, and be compressed by, it. If the fluid is injected warm (80–100° F.) it will diffuse itself more quickly; but *after* it has been injected, the application of ice-bags to the edematized area will markedly intensify its analgesic action. Schleich's infiltrating solutions may be applied in several ways: (1) The field of the operation can be edematized *in toto*—i. e., by infiltration *en masse*, without reference to other anatomic elements—the most typical way; or (2) by *circumferential* infiltration—i. e., by enclosing the field of operation within a wall of anes-

thetizing edema, thus cutting off or isolating the enclosed space from all nerve-communication with the surrounding parts. This last procedure may be applied over plane surfaces, as in the removal of neoplasms, or, in a regional sense, by circumscribing pediculated parts at a distance from the field of operation, as in amputation of a digit, or a limb which is completely infiltrated *en masse* around its circumference, as in the arm, leg, or root of penis. This last mode of infiltration is most successfully applied in combination with the paraneural or intraneural method, as will be seen in discussing the topographic applications of local anesthesia.

For the successful application of the infiltration method in extensive operations, the form of injecting apparatus is of great importance. Until quite recently I was satisfied to use the ordinary hypodermic syringe provided with various needles of different lengths. In more extensive operations an antitoxin syringe (10 cc.

versed so that the pumping is done into the bottle instead of aspirating it. The increased atmospheric tension in the bottle is necessary to force the anesthetic solution into the tissues and to overcome the resistance of the derm and other structures, which is, at times, considerable. Of course, the air-pressure in the bottle can be easily regulated by pumping so that practically any ordinary resistance can be overcome. The bottle used is an ordinary graduated nursing bottle (8 ounce capacity), manufactured by the J. Elwood Lee & Co., for the Lee sterilizer and compress heater. Any strong bottle, graded, of similar capacity, that will stand frequent sterilization, will do. The stopper, with metallic inlet and outlet tubes with stop-cock connections, which is furnished with the Potain aspirator, is adjusted to the bottle and held firmly in position by a special clamp, provided with thumb screws, which permits of adjustment to any bottle of the same size—a necessary pro-

FIG. 1.—Injecting air into bottle containing the anæsthetizing solution. The injector is the ordinary pump of the Potain aspirator with the valves reversed for charging instead of aspirating. The bottle is an ordinary graduated nursing bottle (8 oz. capacity), manufactured by J. Elwood Lee Co., for the Lee sterilizer and compress heater. It is provided with the ordinary Potain perforated rubber stopper which is held firmly in the bottle by a specially devised metallic collar, shield and thumb screws which prevent the stopper from being blown off by the compressed air. The delivery (outlet) and pumping (inlet) rubber tubes are screwed to the nozzles attached to the stopper to prevent accidental detachment during operation. The delivery tube is shorter than shown in photograph No. 2, to facilitate sterilization.

capacity), or a common aspirating syringe of similar capacity, was used, but they had to be filled so often and necessitated so many punctures and interruptions in the work that I finally abandoned the syringes and substituted the simple apparatus which is illustrated in Figs. 1 and 2.

The advantages of an injecting bottle in which the anesthetizing solution could be kept under pressure occurred to me while applying subcutaneous gelatin injections (Lancereaux) in the treatment of inoperable aneurysm. It is practically the same apparatus used for saline infusion (hypodermoclysis) in shock and other conditions, only modified to meet the requirements of analgesic infiltration. The injecting outfit can be easily improvised by utilizing the ordinary Potain aspirator with the difference that the valves of the pump are re-

vision to meet accidental breakage, etc. The clamp is very necessary because, in charging the bottle, the stopper will frequently fly out while pumping, thereby causing much annoyance to all concerned. It is important that all the connections should be made to screw into each other, because if ordinary slip-fittings are used, they will frequently become detached during the course of the operation, causing unnecessary delays and waste of solution. In using the injecting apparatus, the pumping connections are detached and the bottle is inverted and held in this position by an assistant during the process of edematization.

As a rule, I prefer to map out the line of cutaneous incision with a hand syringe provided with a long, fine needle. After the elevated ridge of edema, which is characteristic of intracuticular infiltration, is formed, the

larger and longer needle attached to the injecting bottle is introduced into the hypodermal tissues and the *entire* field of the operation is thoroughly edematized, using for this purpose from 1 to 20 ounces of fluid, according to the extent of the area involved in the operation. The rapidity with which the solution is forced into the tissues as well as the thoroughness with which this is done is surprising. In addition to this the limited number of punctures required to infiltrate a very large area—sometimes one or two punctures are sufficient when a fine 4-inch needle is used—greatly diminishes the traumatism of the tissues and enormously expedites the work.

The contrast between this method and the older, in which ordinary cylindrical hand syringes of small capacity were used, is agreeably apparent and will be readily appreciated by any one who has been operating by the classical methods. Since I have adopted the

the other two. I still continue to apply the 1% solution in direct *intraneural* injections into large nerves, because the effect is much more prompt and satisfactory and because the quantity used for this purpose is very small, the difference in the amount of cocain being insignificant.

In making large massive infiltrations the amount of cocain used and the strength of the solution must be regulated largely by several conditions: first, the possibility of controlling the circulation with the constrictor; second, the quantity of solution that is likely to remain in the tissues for absorption; third, the character and condition of the tissues to be anesthetized; there are regions which are normally more sensitive than others (*e.g.*, anorectal region, genitals, lips, mouth and tongue, face, fingers, etc.), but the most sensitive are the acutely inflamed tissues; fourth, and most important, the possibility, in each instance of anesthetizing the regional

FIG. 2.—Anesthetizing bottle charged and reversed ready for infiltration and edematization. The pumping outfit is detached. The needles shown in the picture are of different lengths and calibers, from 10 cm. (4 inches) to 5.5 cm. (2¼ inches). The caliber varies from Nos. 1-2 (Bleulafoy) to that of a fine hypodermic.

present method I have obtained far more satisfactory results in extensive operations, and have used Schleich's weaker solution, No. 3, with much greater success. In fact, I have learned to rely on infiltration alone more often than formerly, though I still believe that the best results are obtained by combining the infiltration with the neural method. In applying infiltration on a large scale the question of the strength and quality of the anesthetizing fluid assumes great importance.

Up to the last two years I have used cocain exclusively, the percentage of cocain used growing less as my experience increased. In the beginning, in 1885 and 1886, I used with the earlier operators (Corning and others), 2% and 4% solution, but I soon abandoned these and limited myself to 1% as the maximum strength. With the advent of Schleich's researches I adopted his solution, but depended chiefly upon his No. 1 ($\frac{1}{2}\%$) and No. 2, ($\frac{1}{4}\%$), only utilizing his No. 3 ($\frac{1}{10}\%$) on rare occasions, and as a mere adjunct to

nerve-supply. Whenever this is possible the quantity of the analgesic drug is greatly economized.

If we bear in mind the different percentages of Schleich's cocain solutions and remember that 1 grain of cocain is approximately the limit of safety when allowed to remain in the tissues, we will see that about 1 ounce of his No. 1, 2 ounces of No. 2, and 20 ounces of No. 3, can be used with almost complete freedom from all risk. In using these solutions I use No. 1 ($\frac{1}{2}\%$ of 1%) for the intradermal infiltration, and Nos. 2 or 3 according to conditions and the area involved. Lately, since using the injecting apparatus here described I have almost exclusively resorted to eucain B. for the deep infiltrations (Le Grand and Joanin). The fact that it is itself mildly antiseptic, that it can be sterilized by boiling and that it is 3.75 times less toxic than cocain, 5 times less toxic (Vinci), makes it especially valuable for large infiltrations. It is not, in my experience, as effective as cocain, when used in the same

proportions, but in relatively stronger solutions it is equally effective. A 2% solution is nearly as effective as a 1% cocaine, and since it is possible to use as much as 50 or 60 cgm. ($7\frac{1}{10}$ to $9\frac{1}{4}$ grains) in one operation (Sehering and Lohman) and even more without toxic phenomena, its great value cannot be questioned. After numerous trials I obtained the most satisfactory results in major cases with a solution consisting of $\frac{1}{2}$ a grain of eucain B. dissolved in one ounce of an isotonic salt-solution (.8% sod. chlor., Heinze), which represents very nearly $\frac{1}{10}$ of 1% eucain B. Eight ounces of this solution (equivalent to 4 grains of eucain B.) will fill the bottle of my injecting apparatus and is more than is usually required for the large majority of operations. If more solution is required I do not hesitate to refill the bottle until the limit of 10 grains of eucain is reached (20 ounces of solution), provided free drainage of the solution is insured in the course of the operation. In very sensitive parts the strength of the solution may be increased to .2%, 8 ounces of which may be used for the first infiltration, after which a weaker solution must be used so as not to exceed the limit of safety. Larger massive infiltrations than 20 ounces are rarely if ever required, but even then much latitude can be given a judicious operator who will be guided by the loss that is likely to take place through drainage in the course of the operation,—as in the extirpation of carbuncles, large neoplasms, amputations, etc. All that is necessary is to bear in mind the amount that is likely to remain permanently in the tissues for absorption and to see that this does not exceed 5 grains, though experience has demonstrated that 8 and 10 grains are well tolerated.

It is scarcely necessary to insist upon the need of great care in the observance of a rigorous asepsis and more especially a careful personal supervision of the sterilization of the apparatus and of the anesthetic fluid whether they be used for massive edematization or in the small interstitial injections required by the neural method. Fortunately, the problem is easily solved as far as eucain is concerned, since it will stand prolonged boiling without decomposition. Schleich states that the cocaine and morphin that is furnished by the manufacturers (Merek) is usually free from bacteria, but the sodium chlorid is liable to contamination with saprophytes, etc. In my experience the standardized cocaine tablets (Schleich formula) prepared by various American manufacturers (Wyeth & Bro., Sharp & Dohme. and others) are absolutely accurate and reliable and I never hesitate to employ them. The cocaine solutions are prepared by dissolving the tablets in water that has just been boiled and heating the solution *nearly* to the boiling point, the process being repeated several times to secure sterilization by the fractional method. It is generally taught that when cocaine is heated to 176° F. it decomposes into ecgonin and loses its anesthetic properties. Repeated experience has convinced me that cocaine solutions can be heated up to the boiling point for a number of times without losing their efficiency. Peek and Cushing also concur on this point. It has also been pointed out by J. Custer that the toxic power of cocaine, when injected into the tissue, depends less upon the quantity injected than on the concentration of the solution, and that, for instance, the quantity of cocaine in a 2% solution is five times less toxic than a 5% solution. This I believe to be true also of the other analgesic drugs, eucain and nirvanin.

The objections that have been urged against Schleich's method of local infiltration are many. These we shall

not discuss in detail because they have been fully met by Schleich himself in his remarkable book "*Schmerzlose Operationen*" (especially in the last edition, 1899). The method has really suffered more through the efforts of extreme partisans, more especially in Germany, where an unnecessary and fruitless discussion has been waged for some time between the friends of Oberst and those of Schleich. The regional (paraneural) method has been contrasted with the purely local infiltration method, and efforts have been made to exalt the advantages and superior claims of one at the expense of the other. The truth of the matter is as Briegleb, and Schleich himself, has demonstrated, that the methods are not antagonistic to each other and, on the contrary, the best results are often obtained by judicious combination of both. One thing is certain,—that a thorough knowledge of the method of infiltration as taught by Schleich is indispensable to the successful application of the regional or any other method of local anesthesia with analgesic drugs, and that a complete mastery of his technic is of fundamental importance to all those who would aspire to attain the highest accomplishment in this direction. That it is an art that must be acquired by diligent practice and patient observation is undoubted, and this accounts for the many complaints and failures that are heard about it. That it has its limitations is also evident, as we will have occasion to acknowledge. It has been urged, among other objections, that the artificial edema produced by the infiltrations, masks the anatomic characteristics of the tissues, and this complaint has been made even by such friends of the method as von Hacker, Hofmeister, Krecke, Schlatter, and Dipper, but the writer's experience confirms that of Schleich, Mehler, Briegleb, and others, that the edema is not in the least objectionable, even in some of the most delicate anatomic operations. On the contrary, the ischemia produced by the infiltration provides an almost bloodless field, and the writer has never experienced the least difficulty in recognizing the important structures in any of his operations; as, for instance, his numerous ligations of the lingual, external carotid and other vessels in the neck. Neither has he ever observed, as is theoretically claimed by Braatz, that the method is likely to disseminate infection and favor metastasis. On the contrary, the filling of the tissues with a mildly antiseptic solution in a state of tension has appeared to diminish the tendency to infection by filling dead spaces, etc. This is particularly true since the author has adopted the modified method of large infiltration with eucain B., previously described. The objection that it causes severe traumatism by the numerous punctures that are required to cover a large area, and that it consumes much time, is in a great measure overcome by the use of long needles used in connection with the writer's injecting apparatus.

THE REGIONAL METHOD.

Infiltration—Neural Anesthesia.—This term, as applied by the German operators who first made use of it, signifies that a region or area which embraces the prospective field of operation is to be anesthetized rather than the field itself. In this method, the operator, after a preliminary infiltration of the derm, aims at the cocaineization of the deep nerve-fibers which supply the field of the operation. The cocaineization of the nerves that supply the region may be done, as is usually the case in the surgery of the extremities, *at a distance* from the field of the operation; or the nerve-

trunks may be injected *directly* as they are exposed in the region in the course of the operation, as in Cushing's method of cocainizing the inguinal region for the radical cure of hernia. The nerves themselves may be anesthetized: (1) By the *paraneural* method in which the anesthetizing solution is injected in the vicinity of the nerve-trunk, or as closely to the nerve as possible, with the view of enveloping it in an anesthetic atmosphere; or (2) by the direct *intraneural* method in which, after a preliminary anesthesia of the skin, the large visible nerve-trunks that supply the region are brought to view by dissection, and are directly injected with the needle. Practical examples.—To illustrate the application of the *paraneural* method we will select as a good type the procedure that is usually adopted to completely anesthetize a finger for the removal of a nail or for the opening of a felon. The skin at the root of the finger, on its dorsal aspect, is infiltrated over two spots on each side of the phalanx nearest the carpometacarpal joint, and on a level with the web of the hand. The needle is then thrust into each spot and directed towards the known situation of the digital nerves which are deeply situated in the lateral aspect of the digits. From 10 to 15 minims of the anesthetizing solution (1.2% cocain or Schleich's solution No. 1) are diffused in the region of each nerve, with the view of creating a cocain atmosphere around it. After a few minutes' delay, to allow the capillary circulation to diffuse the fluid, the hand is exsanguinated by elevation, and an elastic constrictor is carried around the root of the finger below the seat of infiltration. The finger will then become numb and dead to all painful impressions, and it will be possible to perform any operation upon the digit, at any point beyond the line of constriction. It will be noticed that in this method the nerves of the fingers are not exposed by dissection, but are anesthetized by the diffusion of the cocain solution injected subcutaneously in their vicinity; again it will be noticed that the field of the operation itself (presuming that it is at the tip of the finger, as in a bone felon) is not touched or even approached by the anesthetic injection. In this way the regional method differs radically from local infiltration anesthesia, which if applied for the same purpose would compel the infiltration of the terminal phalanx, or of the entire tip of the finger, and along the line of the incision required, to open the felon. In such conditions the advantages of the regional method are too apparent to require comment. Schleich overcomes the objections to his method at this point by creating a circular ring of anesthetic edema at the root of the finger which involves all the soft parts from the skin to the bone, but without special reference to the nerves. But as in the process of circular infiltration the digital nerves must be reached by the anesthetic, it is evident that he really practises the regional method.

The *regional intraneural method* is excellently illustrated by the procedures devised independently by Dr. George W. Crile, of Cleveland, and by the writer in the amputations of the extremities. If, for example, the case is one in which amputation of a foot, or leg above the ankle, is required, the first step in the anesthetic process will be to expose the sciatic nerve in the upper popliteal space between the hamstrings, and above the point of bifurcation into its peroneal and popliteal branches. In order to expose the nerves clearly, the skin and popliteal fascia must be anesthetized by infiltration with a weak 2% Schleich solution. After exposing the nerve and bringing it out well to view, from 20 to 40 minims of a Schleich solution No. 1, or 10 to 20

minims of a 1% solution, are injected into the nerve, until an edematous swelling is formed indicating that the entire thickness of the nerve has been "blocked" or infiltrated; the wound is then packed with sterile gauze, and aseptically protected, and another incision is made over the long saphenous nerve in the leg, which is also infiltrated; this wound is closed with sutures. The limb is then elevated and drained of blood by gravity, and after it has been exsanguinated the constrictor is applied above (centrad of) the incision made to expose the sciatic. By this time, or after a few minutes' delay, the entire lower limb below the sciatic incision will have become completely anesthetic, and an amputation or any other operation can be performed without the least pain as long as the constrictor is kept in place. In amputations or extensive operations at a higher point than the tubercle of the tibia the anterior crural must be injected instead of the saphenous. In this way again the region or field of the operation is completely anesthetized and yet it is not touched by the anesthetizing solution. The same regional method by intraneural injection is beautifully illustrated in the upper extremity, which can be entirely anesthetized by exposing and injecting the brachial plexus above the clavicle; and in the operations below the elbow, where I prefer to anesthetize by the direct injection of the ulnar, median, and musculospiral nerves. The principle is again admirably illustrated in Cushing's operation for the radical cure of hernia, previously referred to.*

THE MIXED METHODS.

These are applied: 1. When two or more local anesthetics are utilized in the course of the same operation (*e.g.*, ethyl chlorid and cocain; cocain and eucain B; cocain and nirvanin, etc.).

2. When the local anesthetic action of cocain, or other similar analgesic drugs, is preceded or supple-

*The paralyzing effect of cocain upon the nerve is proportional to the duration of the application, the size of the nerve and the concentration of the solution. Strong solutions, 5%, act immediately; weaker solutions, $\frac{1}{2}$, $\frac{1}{10}$ of 1% act slowly but effectively. François Franck found that 5 to 10 mgm. ($\frac{1}{4}$ to $\frac{1}{2}$ gr.) were sufficient in animals. The paralyzing effect is variable in duration according to the dose applied and the size of the nerve involved, but the isolation of the peripheral organs which have been cut off from the nerve-centers is usually of sufficient duration even with weak solutions to permit of comparatively long operations. On the other hand, the action of the drug is continued indefinitely and, if anything, intensified by arresting the circulation of the anesthetized nerve-trunk. If the circulation is not interfered with, the paralyzing influence of the cocain will extend 1 to 2 cm. above and below the points of contact with the drug (F. Franck). The rules laid down by Franck in his remarkable experiments on animals are as valuable to the surgeon as to the physiologist. The first rule is that the dose of cocain applied to a nerve should always be sufficient to paralyze it locally and insufficient to provoke general toxic phenomena after its absorption. These doses he carefully estimated for the animals experimented upon. 2. The application of cocain must be limited to the nerve that it is intended to suppress functionally. This refers to the dangers of cocainizing the important visceral and motor nerves of the neck, *e.g.*, the phrenic, which, as demonstrated by Mosso as early as 1885, will suspend its function and cause a cessation of diaphragmatic respiration when directly cocainized. In these cases the animals are only saved by artificial respiration which must be kept up until the drug is eliminated. Equally serious but different disturbances attend the direct infiltration of the pneumogastric. The mode of cocainizing the nerves was thoroughly studied by Franck. He tried various methods, bathing the nerves with cocain solution, pledgets of cotton soaked in solution, direct application of the crystals of the salt, cocain vaseline, etc., but he finally adopted the method of direct infiltration into the nerve sheath, by interstitial injection, as the most reliable and accurate method. The nerve is never damaged by this procedure when it is carefully done with a fine needle.

The paralyzing action of cocain on nerves was studied by various experiments long before the possible use of this knowledge in surgical practice had been suspected. Van Anrep (1880), Laborde (1884), Charlier (1884), Lafont (1884), H. W. Biggs (1885), Lukahewitch (1884), etc., and many others devoted their attention to the subject before the importance of Kohler's clinical discoveries had been at all appreciated. The majority of investigators subsequently devoted special attention to solving the problem of cocain action on mixed nerves, which from the earlier experiments of Van Anrep had been erroneously believed to be limited to the sensory fibers alone. Doubts still existed on this point until C. Mosso in a conclusive and most exhaustive review of the work done by all his predecessors, clearly demonstrated that cocain acted on all nerve-fibers alike as a paralyzing protoplasmic poison, a view which he had held since 1885. To his learned paper in *Gior. della R. Accademia di Med. di Torino*, serie III, xxxviii, and to the later paper by Ch. A. François Franck (*Archiv de Physiologie normale et physiologique*, vol. 4, 5me serie, 1892), the writer is chiefly indebted for the data quoted in this note.

mented by the action of a cerebral anodyne—morphia (mixed morphin-cocain anesthesia, Ceci).

3. When in addition to morphia the local anesthetic action of cocain or other local analgesics (eucain B., nirvanin, ethyl chlorid, Bloch) is preceded or supplemented by the effects of a general inhalation-anesthetic, such as chloroform ("morphin-cocain-chloroform anesthesia," Schleich, Cushing). While, as a general rule, the combination of one local anesthetic in addition to cocain is unnecessary or superfluous in general infiltration or regional anesthesia, there are occasions when, in order to diminish the possible occurrence of toxic phenomena from the too liberal use of even very dilute solutions of cocain, it may be advantageous to utilize the anesthetic properties of its less toxic succedanea. Thus, in the removal of large tumors of the neck, of carbuncles, etc., in which the circulation of the region cannot be readily controlled, we resort to cocain solutions (No. 1, Schleich) for the infiltration of the most sensitive parts of the field of operation (*e. g.*, the skin), and depend on eucain B. in .2% solution for the general edematization of the remaining and less sensitive areas. I have also systematically depended upon the combination of the anesthetics in operations on the bladder in which the topical application of strong, local anesthetic solutions is required to anesthetize the sensitive and inflamed mucosa. This occurs most frequently in suprapubic cystotomy for stone or for the relief of prostatic obstruction. In these cases I inject the bladder first with a 2% or 4% cocain solution, according to the degree of sensibility. I follow this with a more liberal use of solutions of eucain B. (4%), or of nirvanin (5%), which are allowed to remain in the bladder while the suprapubic region is cocainized with the Schleich (.2%) solution. In the performance of litholapaxy by Chismore's method, which I have resorted to 7 times with 6 complete successes within the last 2 years, I have begun the anesthesia of the urethra and bladder with a preliminary injection of a 2% solution of cocain; after allowing this to remain 15 to 20 minutes or longer (according to tolerance) in the bladder, I have followed with a 4% eucain B., of which 4 and 6 ounces have been used during the course of the operation. In the last two cases I adopted the plan of making the first application with cocain and continuing for the remainder of the sitting with a 5% nirvanin solution, which I have found very satisfactory as a topical anesthetic in such cases. Before the discovery of nirvanin by Einhorn and Heinze (1898), I also used, in bladder cases, an emulsion of orthoform (10%), which I also found to be a good topical anesthetic for all mucous membranes; but since the introduction of nirvanin, which is a soluble form of orthoform, I have given the preference to this more elegant and efficacious preparation.

The administration of morphia, one fourth grain hypodermically, 15 to 30 minutes before beginning a cocain operation, has been found to be most valuable in all cases in which any extensive or lengthy procedure is contemplated. It is especially valuable in nervous, timid, emotional patients. In this as in all other cocain cases a liberal toddy or a good draught of hot tea or coffee or of panopepton will materially help to prepare the patient for the mental ordeal. There are very few cases in which the preliminary use of morphia is contraindicated; the exceptions are those who suffer from idiosyncrasy against it, or the very aged in whom the constipating and general disturbing effects of the drug on the eliminating organs and alimentary canal are

especially to be avoided; but even in such cases the good that is derived from the soothing and anodyne effect of the drug more than counterbalances the post-operative effects. Morphia used as a preliminary analgesic, has also, as a rule, a most favorable action in preparing the patient for a general anesthetic, such as is required to soothe the psychological excitement or other neurotic perturbations that often occur in the course of long and tedious operations. The conditions in which I have been able to use the combined morphin-cocain-chloroform methods are numerous and will be again referred to in considering the topographic technic of local and regional anesthesia. It may be stated in a general way, however, that this mode of combining the anesthetics is chiefly reserved for two classes of cases; one in which the emotions and the excitable temperament of the patient act as a serious disturbing factor in the course of the operation, by preventing the thorough performance of surgical work (even though there be a total anesthesia of the field of operation); and the other, the more important class, in which it is particularly desirable to economize the administration of a general anesthetic for more organic reasons, such as exist in septic, hemorrhagic or exhausted cases in which fatal shock and exhaustion are particularly liable to occur. Preliminary abdominal exploration under cocain has therefore come to be regarded in many large clinics as a regular procedure in a constantly increasing number of cases. Its advantages in saving the patient from the disastrous effects of prolonged and saturating anesthesia are so obvious that this mode of procedure needs only to be mentioned to be appreciated. It is also fortunate that in the majority of the cases in which prolonged general anesthesia is most dangerous that the least quantity of anesthetic is required, provided the more painful stage of abdominal section has been bridged over with the help of cocain. It has been the writer's experience that in a profound septic condition, as in cases of suppurative peritonitis from appendicitis or from perforations in the gastrointestinal tract, in cases of strangulated hernia, in intestinal obstruction, in the profound collapse caused by traumatic or other hemorrhages in the peritoneal cavity, and in marasmic patients exhausted by prolonged starvation (esophageal stricture, pyloric stenosis), very little—almost an infinitesimal quantity of chloroform is required to produce a condition of insensibility which is perfectly compatible with satisfactory surgical work, provided the section of the abdominal wall has been painlessly accomplished with the aid of a preliminary cocain infiltration.

In the preceding sections which refer to the definition and classification of the present methods of local and regional anesthesia, with the exception of the sub-arachnoid method, which we shall consider separately, we have briefly outlined the general principles which underlie the general application of these methods. It would now be proper to consider the special technic by which these general principles and methods can be best adapted to meet the exigencies of surgery in the various regions of the body. This topographic study of the subject the writer has already fully and systematically attempted in his recent mimograph, published in the Transactions of the Louisiana State Medical Society, and again proposes to elaborate in greater detail in a work which he will soon submit to the press. He will only attempt on this occasion to present a few of the more striking applications of the infiltration and neuro regional methods as he utilizes them in his practice.

THE EXTREMITIES.

The Fingers and Toes and their Metacarpals.—The methods available here are the neuroregional and the infiltration method alone or combined. For these parts of the extremities the methods indicated in Figs. 3 and 4 are invariably used in the author's clinics, and with unfailing success. The paraneural injection of the digital nerve is known variously in Germany and

FIGS. 3 AND 4.—*Hand 1.*—Showing point of injection in the regional anesthesia (paraneural method) of the fingers alone. The lower points indicate seat of deep injections to reach the digital interosseous and palmar nerves (paraneural method). The linear outline over metacarpal of index indicates area of artificial edematous infiltration "regional paraneural infiltration method" for disarticulation of index and its metacarpal. *Hand 2.*—Two points at base of thumb indicate seat of deep (paraneural) injection of the digital nerves to control sensibility of thumb. These may be combined with a ring of dermal infiltration at the same level "regional paraneural infiltration method" encircling the digit. The outline over the first metacarpal indicates area of edematization associated with two deep interosseous injections to anesthetize entire thumb and its metacarpal, as in corpo-metacarpal disarticulations (regional paraneural infiltration method).

France as Oberst's, Krogius, Braun's, and Kummer's methods. Contrary to the German method, the constrictor is applied *after* the infiltration, and the anesthetic fluid is allowed to diffuse itself as Corning originally suggested, before exsanguination and constriction. In operations on the metacarpals, the constrictor is applied above the elbow. The points of paraneural injection are made with Schleich's $\frac{1}{2}$ of 1% solution or a 1% solution, according to the sensitiveness and extent of the area. The points usually selected for the deep injections are indicated on the figures, and the areas of general edematization with the 2% eucain B. solution are also outlined in the figures.

The Hand, the Wrist, and the Forearm.—The complete anesthesia of these regions may be obtained in part or in whole, by any one of the following methods: 1. General infiltration (Schleich), which may be applied like a bracelet, circumferentially, around the limb, at any level from the wrist to the shoulder, in thin and emaciated subjects especially. 2. Paraneural infiltration (subcutaneous) method in which the infiltration is more or less limited to the region of the nerve-tracts, as practised at the wrist and elbow by Manz, Hölcher, Berndt, Le Fort, Reclus, and others. 3. Regional direct (open) intraneural infiltration with or without the help of circular dermohypodermal infiltration. The infiltration method alone at the wrist or forearm is especially indicated in thin and wasted subjects; it is most effective when reinforced by the paraneural method, which selects the radial, median, and ulnar nerves in the field of the operation,—as in amputations. The paraneural method is unsatisfactory when practised without massive infiltration by the method recommended by the author, and will yield uncertain results as admitted by Manz and Honigman, who have especially advocated the method. On the

other hand, the direct intraneural method is infallible and will completely anesthetize the hand and wrist up to the junction of the middle and lower thirds of the forearm if the ulnar, median, and musculospiral nerves are separately isolated and injected, as is indicated in Fig. 5.

In operations on the upper forearm the injection of the three great nerves at the elbow will produce absolute insensibility of all the extremity up to the point of injection except the skin of the upper (central) half of the forearm, which is supplied by the overlapping fibers of the internal and external cutaneous nerves. In order to abolish this superficial sensibility a dermohypodermal infiltration applied with the writer's injecting-apparatus, and carried circularly around the arm above the elbow on a level with the neural injections will completely overcome any remnant of sensibility in the distal side.

The open intraneural method of cocainization of the three nerves at the elbow is undoubtedly the most effective and reliable means of securing the anesthesia of the parts below (peripheral to) the points of injection. It has the advantage that it can be applied on stout,

FIG. 5.—Surface anatomy of arm showing regional infiltration intraneural method of anesthesia as practised by the author to obtain insensibility of the entire hand and forearm. A zone of anesthetic dermohypodermic infiltration encircles the arm at the bend of the elbow (shaded zone). The arm is then exsanguinated by elevation and the constrictor is applied at the axillary level. Three incisions are then made to expose the musculospiral (M.S.) the ulnar (U.L.) and the median (M.) nerves. Each nerve is then injected separately with the anesthetizing solution. The entire hand and lower third of forearm can be anesthetized by a similar process, except that chief reliance is placed upon the zone of infiltration which edematizes all the tissues en masse down to the interosseous membrane, separate stronger paraneural injections being made along the tracts of the median (M.), ulnar (U.L.), and radial nerves (regional infiltration paraneural method).

muscular subjects as well as the wasted and emaciated. But it is a strictly anatomic procedure which cannot be done rapidly, and is for this reason not likely to be popularized except in the clinics of surgical specialists.

The practicability of this method suggested itself to me in 1897, but no opportunity presented itself for its application until January, 1898, when an old man, aged 76, applied to my clinic for the relief of an extensive and deep epitheliomatous ulcer which involved a large part of the dorsal and hypothenar regions of the right hand. The patient was profoundly arteriosclerotic; his radials were hard and rigid as pipestems and his heart was the seat of loud aortic and mitral murmurs which indicated advanced valvular lesions. He was a decidedly unfavorable subject for general anesthesia and I decided to anesthetize the hand by the direct neuroregional method. The musculospiral, the median, and the ulnar were readily and painlessly exposed (under infiltration anesthesia, Schleich, No. 1) by separate incisions made over the region of the individual nerve-tracts where they are most superficial at the bend of the elbow; the nerves were then exposed and each injected with 5 to 8 minims of a 1% cocaine solution. This caused a slight fusiform swelling at the point of injection. The wounds were sutured, but the threads were not tied, to provide for further injection, and the entire region was protected by a carefully applied aseptic dressing. The arm was then exsanguinated by elevation and the elastic constrictor was applied over the middle of the arm. The anesthesia of the extremity was now complete from the finger nails to the elbow. We were then able to extirpate the growth very freely, including the fourth and fifth fingers with their metacarpals and the corresponding palmar and dorsal aspects of the hand, proceeding throughout with all the freedom that is permitted by general anesthesia. After completing the work in the hand the incisions at the elbow were closed by tying the knots of the loose catgut-sutures, which had been purposely left untied, before the constrictor was removed. The operation in this way was not only painless but bloodless. Before the operation the patient was given an hypodermic consisting of $\frac{1}{4}$ grain morphia, $\frac{1}{16}$ grain strychnia, $\frac{1}{160}$ grain digitalin.

Since the first operation (January, 1898) was performed, the procedure has been repeated by myself several times and once by my friend and assistant, Dr. Larue. In all these cases the intervention was necessitated by bone lesions of either the hand, wrist, or forearm. In all of these cases the patients were able to walk to their beds after leaving the operating table. None suffered from the least shock or constitutional disturbance and in none were the postoperative sequelae such as to suggest that any injury had been done by cocaineization of the nerves. All the small wounds made to expose the nerves healed kindly under the usual aseptic dressings. In all of these cases the anesthesia of the regions tributary to the nerves injected continued for a variable period, from 15 to 20 minutes after the removal of the constrictor.

The Shoulder and Arm, Including the Entire Upper Extremity.—The arm can be amputated at any level, including the scapulohumeral articulation, by infiltrating the brachial plexus as it leaves the scaleni in the supraclavicular fossa. The credit of this brilliant demonstration of the regional intraneural method is entirely due, I am pleased to state, to an American surgeon, Dr. George W. Crile, of Cleveland, Ohio. It was with the view of diminishing shock that Dr. Crile, whose remarkable and exhaustive experimental studies on shock have made his name familiar to all readers of surgical literature, was led to apply this method which, following F. Franck, he appropriately designates "the blocking method."

In a personal communication addressed to me, August 24, 1899, Dr. Crile stated that he had operated by the

"blocking" method up to that time, on seven patients, one of these being a case of amputation at the shoulder-joint, anesthetized by "blocking" the brachial plexus above the clavicle. Dr. Crile's first case of amputation of the leg was reported to the Ohio State Medical Society in 1897, and excited the attention of that body, but the great merit of his performance has failed of sufficient general recognition as one of the most brilliant and useful contributions to the technic of regional anesthesia that have emanated in recent years from an American surgeon.

While the brilliant results of the open neuro-regional method, as applied to the brachial plexus, are most striking in the hands of a skilful operator, the advantages of general massive infiltration and edematization on the Schleich plan in thin persons are not to be disregarded. In pathologic conditions, especially advanced and irreparable tubercular lesions of joints, and humerus necessitating amputation, it is most effective. Recently, my able assistant, Dr. Gessner, very successfully amputated the lower third of the arm with the help of infiltration alone. Schleich ("Schmerzlose Operationen," 1899), Reclus ("La Cocain en Chirurgie," 1896); Haberen ("Grössere Operationen unter lokaler Anästhesia"); Ungar (*Med. Press*, 1897, ii), T. Wikerhäuser ("Operationen mit Schleichscher Analgesia," *Centralbl. f. Chirurg.*, October 21, 1899), the writer and many others have reported similar cases.

These successes, however, do not mean that Schleich's infiltration method alone is applicable to *all* cases, they only emphasize the necessity for eclecticism in the selection of cocaine methods, local as well as general.

The Lower Extremity.—What has been said of the upper extremity may be in a great measure repeated of the lower limbs. The general principles and methods are the same except that they vary in their topographical application. The infiltration, the paraneural infiltration, the regional *open*, the intraneural, and the spinal subarachnoid methods can all be utilized with advantage according to the regions involved and the local and constitutional indications furnished by the patients themselves.

The infiltration method with weak solutions according to Schleich, with or without constriction, and the mixed infiltration neural methods are alone able to meet a vast number of indications. The ligations of *all* the arteries, from the external iliac (R. N. Hartley, Leeds, 1895) to the dorsalis pedis, have been made subservient to the infiltration method. Amputations from the toes and their metatarsals to the middle third of the thigh have been repeatedly performed with it. And a great number of major operations on the bones and joints, including the femur, have been reported, from the earlier amputation of the thigh by Variek (1886) and osteotomies by Josiah Roberts (1885) with the Corning method to the later cases by Schleich, Trapani, Rhodes, Cowan, and Wikerhäuser, who reports (Operationen mit Schleichscher Analgesie, *Centralbl. f. Chirurg.*, October 21, 1899, Abst.) 18 extensive bone operations out of a list of 113 major operations in which sections of the thigh and leg bones were required. All of these reports, which could be multiplied many dozen times, simply confirm the statement previously made that the operator should not be wedded to any single method, but knowing the capabilities of each can select his technic and at times obtain surprising results with a method that would appear to the inexperienced as theoretically inadequate to meet the demands of the case.

But, in spite of the numerous interventions on the lower limbs which have been obtained by *simple infiltration* with the Corning or Schleich methods, it must be recognized that these successes have been (with the notable exception of the toes and their metatarsals) more conspicuous by their rarity than by their frequency. They simply illustrate what can be done with the method in exceptionally favorable conditions both

FIG. 6.—Surface anatomy of lower extremity showing superficial points where the external cutaneous (E.C.) and anterior crural (A.C.) nerves can be exposed as they emerge under Poupart's ligament. The infiltration of these nerves will give complete control of the sensibility of the thigh except the upper and inner half. The circular zone of infiltration (C.Z.I.) if carried deeply so as to edematize the entire circumference of the limb (in wasted, emaciated subjects) will suffice without special neural injection (except into the sciatic) to completely control the sensibility at and below (peripheral of) the infiltrated zone. The zone of dermohypodermal infiltration is far more important posteriorly to control the sensitive fibers of the lesser sciatic and is necessary, in connection with infiltration of the greater sciatic, in all operations involving the lower half of thigh and knee. In this last class of cases the circular infiltration need not be pushed deeper than the aponeurosis.

as regards the morale of the patient and the favorable anatomic condition of the parts. This is particularly true of all extensive operations involving the skeleton of the foot, leg or thigh in robust, fleshy subjects. In this class of patients local anesthesia is, as a rule, inadequate, and when an excision of a large joint (the ankle or knee), or when a large sequestrotomy, osteotomy or an amputation is contemplated, a method more positive and reliable is required to accomplish the intervention with that freedom of action that can only come from the absolute analgesia of the entire region involved. It is precisely under such circumstances and when the contra-

indications to general anesthesia are positive that the regional intraneural method can be confidently appealed to. For the purposes of neuro-regional anesthesia, as we understand it, the lower limb may be divided into three topographic areas: (1) the toes and their metatarsals; (2) the large area which includes the tarsus, ankle, leg, and knee, up to the middle of the thigh; (3) the thigh including the knee.

Neuro-Regional Infiltration in the Lower Extremity.—All operations, no matter what their extent, which involve these regions, can be painlessly performed by a single method, viz., the open intraneural cocaineization of the sciatic and of the long saphenous, or of the anterior crural and external cutaneous nerves in the higher operations, above the knee. This comparatively simple and thoroughly reliable procedure we owe, as has been already stated, to Dr. Geo. W. Crile, who applied it for the first time in a case of amputation of the leg in 1897. Crile's method of "blocking" the sciatic and crural nerves is infinitely more practical and satisfactory than the purely paraneural methods suggested for these regions by O. Manz (1898), and F. Berndt (1899), who have reported several cases in which the anesthesia of

FIG. 7.—Surface anatomy of the lower extremity showing incision to expose the greater sciatic nerve (G.S.) and zone of dermohypodermal infiltration encircling the thigh. In extensive operations requiring anesthesia of the foot or leg (amputations, excisions, etc.), the intraneural injection of the sciatic and paraneural infiltration of the long saphenous below the knee will suffice to completely control the sensibility of the limb. In operations involving the knee or the thigh the zone of dermohypodermal injection (C.Z.I.) together with the injection of the external cutaneous and anterior crural becomes necessary.

the foot, ankle, and knee (Griffith's operation by Berndt) has been obtained by injecting subcutaneously the indi-

vidual branches of the sciatic at various levels in the ankle, leg, and thigh.

Without any previous knowledge of Crile's work, and encouraged by other successes with the same method, as applied to the upper extremity, I performed a Pirogoff operation for frost-bite by this method in March, 1899. From March, 1899, to the present date, I have availed myself of this mode of anesthesia 7 times, my colleagues, Drs. Parham and Perkins, operating on 3 other cases in their services at the Charity Hospital. In all my 7 cases there were reasons which made the administration of a general anesthetic undesirable. In one of these, operated on before the medical class of Tulane University, the inestimable advantage of possessing a reliable and safe method of analgesia as an alternative to general narcosis was made particularly apparent. This case not only illustrates the circumstances in which this method is especially applicable, but it will serve to describe the technic of the method as well.

F. S. W., aged 32, was admitted to the hospital, December 18, 1899, for the treatment of a diffuse suppurating tubercular arthritis of the right tarsus. The patient was suffering with advanced pulmonary tuberculosis (cavity in lung), but his sufferings were so great that an operation was decided upon. In view of his weakened condition, special precautions were taken to guard against the accidents of general anesthesia. In addition to the preparatory administration of strychnia, digitalis, and nitroglycerin by hypodermic, the nares were sprayed with a 2% cocain solution to diminish the nasolaryngeal reflexes (Franck-Rosenberg). Chloroform was then administered over an Esmarch mask by the "guttatim" method. Notwithstanding all the care taken, the patient rapidly entered into a most violent stage of excitement and became rigid and cyanosed; respiration was arrested, the pulse became irregular and imperceptible and when the tetanic rigidity ceased the patient sank as if completely collapsed, and it was only by the immediate application of artificial respiration and other measures, that he finally came back to consciousness again. As the operation was imperative and all general anesthetics were not to be thought of (ether being contraindicated by the phthisis), I decided to try the intraneural method of regional anesthesia—which should have been the method of election at the start. Accordingly, after careful preparation of the parts, the skin and underlying tissues of the upper popliteal space were infiltrated with a Schleich No. 1 cocain solution, and an incision four inches long was made so as to bring the sciatic nerve into view. This done, an injection of 25 minims of the same No. 1 ($\frac{1}{2}$ of 1%) solution was injected into the trunk of the nerve. A constrictor was applied—after exsanguinating the limb by elevation—care being taken to pad the limb well so as to minimize the discomfort it might produce. Eighteen minutes after the injection of the cocain, some sensibility still existed in the foot; fearing that the weak solution would be insufficient, 20 minims of a 1% cocain were then injected into the exposed nerve. In three minutes the anesthesia of the entire region below the sciatic infiltration was complete and the operation was begun 20 minutes after the first injection into the nerve had been given. The tarsus was then explored by making a free extero-lateral incision and all the bones, including the tarsometatarsal articulation, were found to be involved in a diffuse tuberculosis. The astragalus alone was saved. The chisel, gouge, and bone curet were used freely with the hope that a simple excision might suffice, but the lesions of the skeleton and soft parts, including the tendon sheaths, were so extensive that an atypical sub-astragaloid amputation was decided upon. The patient, who had been perfectly quiet and passive, was now asked his consent to the amputation, which at first he refused, but after showing him the extent of the lesions and explaining to him the advantages of a radical extirpation in a man in his condition, he consented, and the amputation was performed. The patient gave us very material assistance in this operation, not only by holding his foot and leg in the most favorable attitudes for our work and by turning his body around without assistance when at the termination of the operation on the foot we closed permanently the sciatic incision. The

contrast between the alarming condition induced by the general anesthetic (chloroform), and the passive and calm attitude of the patient throughout the operation was most impressive.⁵

The only complaint made was at the end of the operation, caused by the constrictor at the thigh. The pain from the pressure exercised by the constrictor becomes at times intolerable in operations which last as long as an hour. The constrictor should always be relaxed when it causes serious annoyance, provided hemostasis has been accomplished. Even if pain is not seriously complained of from this source, it is important to allow the circulation to reestablish itself, if only for a few moments, to prevent the possible nutritive disturbances that often follow prolonged ischemia in inflamed and badly-nourished tissues. The mode of applying the elastic constrictor or the tourniquet over soft pads and in a spiral manner, so as to avoid concentrated linear pressure at a single level, is very important to insure the comfort of the patient.

The operations successfully performed by this method in my practice have been (1) Pirogoff's amputation for frost-bite; (2) Syme's operation; (3) two atypical resections of the tibio-astragaloid joint, in which the astragalus and calcaneum were excised together with the tibio-fibular surfaces and their malleoli, for tuberculosis; (4) Guyon's supramalleolar amputation of the leg for trauma; and (5) an extensive search in the thigh for a lost bullet imbedded in the neighborhood of Hunter's canal. In the last case the anterior crural nerve and external cutaneous were cocainized under Poupart's ligament. In this case we were misled in the situation of the bullet as indicated by radiographs and failed to find the bullet even after a most extensive dissection in the lateral and posterior femoral aspects of the thigh had been made.

Head, Face, and Neck.—The application of local infiltration and regional anesthesia to the major surgery of these parts is greatly hampered and hindered by the difficulty of effectively reaching the most important nerve-trunks and by the inability to control the circulation, except in a few favorable areas. Nevertheless, surprisingly brilliant results can be obtained with these methods by those who are adepts in their application and who are alert for opportunities to substitute them for general narcosis. At present the control of the circulation is still desirable, not so much to diminish the dangers of intoxication, but to prolong and intensify the action of this narcotic drug in long operations. The demand for appliances to "incarcerate the anesthetic" is shown by the invention of numerous devices, such as Corning's scalp-rings, Corning's hemostatic fenestrated forceps for operations on the cheek, mouth, and breast, Noyes' ectropion forceps, Wright's clamp, etc. At present the introduction of Schleich's infiltration anesthesia has made these devices unnecessary, except in regions in which the anatomic configuration of the parts (scalp and auricle) will permit of easy elastic constriction, which is always advantageous, if only from the hemostatic point of view. The utility of Corning's principle of incarceration was most forcibly impressed upon my mind in 1890, in operating upon an extremely vascular nevoid angioma of the entire auricle.⁶

⁵ This and other cases illustrating regional intraneural and spinal coesulization as they have presented themselves in my clinics at the Charity Hospital have been reported in interesting graduation theses by Drs. Samuel Logan and B. A. Terrett, of the Tulane class of 1899-1900.

⁶ "A large cavernous angioma involving the integument of the entire auricle, successfully treated by dissection, resection of the diseased tissue, and ligation of the afferent trunks *in situ*, by a special method," by R. Matas, M.D. (*Medical News*, December 24, 1892.)

In this case the ear presented elephantine proportions and pulsed with the arterial and venous blood furnished by enormously dilated bloodvessels. One of the caverns ruptured by ulceration and the patient nearly succumbed after a frightful hemorrhage. The external carotid was ligated, but this was followed by only temporary improvement. A few weeks afterwards the ear was cocaineized, resected, and bared completely of its tegumentary covering, including the afferent bloodvessels which were all secured and ligated by a very simple procedure. This consisted in the injection of a 4% cocaine solution ($\frac{1}{2}$ of 1% would have been sufficient) into the periauricular tissues at the root of the ear until a complete circle of cocaine solution had been formed around it (circumferential infiltration). Four hare-lip pins were then introduced at equidistant points so as to transfix sections of the circle. These were used as binding posts to hold a thin rubber band which was wound around each pin and the rubber was stretched tightly around the pedicle. The rubber in this way was held fast and prevented from slipping. The pulsations in the ear ceased immediately and with the arrested circulation a complete anesthesia of the auricle followed, which permitted the operation to be performed throughout without pain or hemorrhage.

In operations upon the scalp I also depend upon constriction with a heavy elastic cord wound around the forehead, just above the glabella, the temporal fossa, and the external occipital protuberance. The temporal fossae are compressed sufficiently to arrest the flow in the deep temporal arteries by threading the elastic into perforated wooden blocks, shaped like elongated trun-

FIG. 8.—Diagrams illustrating author's method of controlling the circulation and of prolonging the effect of cocaine anesthesia in extensive operations on the auricle. The anesthetic solution is infiltrated around the pedicle of the ear by circumferential infiltration. The pins are used by bridging posts to prevent the elastic from slipping when excision or amputation is required, as in vascular neoplasms.

ated pyramids, which fit the temporal fossae and exercise the necessary pressure. By this process hemostasis of the entire scalp is obtained and the anesthesia is indefinitely prolonged. In suturing extensive scalp wounds, in removing multiple sebaceous cysts and other tumors, in exploring the skull for injury, in craniectomy (this has been done repeatedly with the chisel by Schleich), and trephining for depressed fracture, in the evacuation of epidural hemorrhages, of intracranial abscesses, etc., the scalp and periosteum can be sufficiently cocaineized to permit of painless operating. In operations upon tumors and cysts of the scalp a circumferential infiltration, encircling the field of operation, is usually effective. In more extensive cases an outer circle of edema can be made with cocaine. (Schleich No. 1), and the enclosed area is totally edematized with weaker cocaine solutions (Nos. 2 or 3), or with the .2% eucain B. previously described.

Usually in the severe traumatism of the skull, such as extensive compound or simple depressed fractures, the patients are in a state of unconsciousness or stupor from shock, or brain injuries, which permit of painless operating with very little local anesthesia. On the other hand, if there is delirium, restlessness or much cerebral irritability, local anesthesia cannot be practised with ad-

vantage and chloroform must be administered. Leaving out of consideration the surgery of the eye, in which local anesthesia is preeminently successful, or that of the intranasal passages and of the external ear, in which cocaine anesthesia is also most valuable, we find that local (infiltration) anesthesia finds many restrictions in its application to the major surgery of the face. Nevertheless, with a fair knowledge of anatomy and a large experience with cocaine technic, some remarkable operations can be performed by this method.

The following case taken from my note-book will illustrate the value of regional anesthesia in a class of cases usually regarded as unapproachable with cocaine.

Partial excision of both upper maxillae and entire hard palate for malignant disease under regional anesthesia.—A white man, laborer, aged 48, addicted strongly to alcohol for years and suffering with advanced arteriosclerosis, was admitted to Ward 7, Charity Hospital (April 29, 1899), for treatment of a recurrent epithelioma of the palate involving the anterior alveolar arch and both upper maxillary processes. The neoplastic infiltration extended to the right half of the palate and along the entire incisor region to the first right bicuspid; the anterior half of the hard palate also presented a large, ovoidal swelling caused by malignant periosteal invasion. I decided that I would try to remove the entire hard palate, including both palatine processes of the upper maxilla, the floor of the antrum and the septal cartilage of the nose. I also decided to anesthetize these parts by infiltrating the superior maxillary divisions of the trifacial in both sphenomaxillary fossae, but promised the patient that I would administer chloroform if he felt, at any time in the course of the operation, that the pain was unbearable. A hypodermic of morphia, $\frac{1}{4}$ grain, was given 20 minutes before the operation. In order to anesthetize the maxillaries and the palate the sphenopalatine fossae were filled with a No. 1 Schleich solution introduced by a long needle introduced through the floor of the orbit into the sphenomaxillary fissures. The needle was directed as closely as possible through the fissure in the right orbit towards the infraorbital nerve as it enters the infraorbital canal. In this way it was expected that not only the entire superior maxillary division of the trigeminus could be anesthetized, but that Meckel's ganglion with its palatine branches would be "blocked" by the anesthetic. In a few minutes we tested the sensibility of the cheeks, lips and alae of nose and were gratified to find that the entire cutaneous distribution of the infraorbital had been completely anesthetized on the corresponding (right) side. Encouraged by this result, the left sphenopalatine fossa and infraorbital nerve were treated in the same manner, with identical results. Fully fifty minims of Schleich's No. 1 solution, reinforced by 25 minims of 1% cocaine, were injected into each sphenopalatine fossa. The nasal septum, which is supplied by the nasopalatine and the nasal branch of the ophthalmic, was controlled by a separate infiltration, a long needle being introduced through the frenulum of the upper lip and into the root of the columna and septal cartilage of the nose. The anesthesia of the posterior palatine nerves was also reinforced by direct infiltration in the posterior palatine foramina. When the last injection had been completed the patient said that his palate and face felt entirely "numb" and gave the impression of a "dead block of flesh" wedged in his face. The anesthesia of the jaws was then tested by extracting a perfectly sound right canine which was firmly implanted in its socket. The patient was surprised when he saw the tooth, saying that he had not felt the least pain in its extraction. The upper lip was then divided in the median line and detached from the nose by two lateral incisions which were carried along the lower border of the columna nasi and to the nasolabial groove. The lips were then dissected away from the gums and jaws as far back as the tuberosities of the maxilla. The two halves of the upper lip were then reflected outwards and held out of the way with loops of strong silk which acted as retractors. A very sharp McEwen's chisel was then driven by hand into the body of the right maxilla on a level with the floor of the nose. With a few sharp strokes of the mallet, the palatine process including the tuberosity was divided and

the antrum was exposed; the same process was repeated on the other side, and the separation of the septum nasi from the jaws completed the line of osseous section. In this manner the lower half of both upper jaws and the entire hard palate with the attached growth were mobilized and displaced downwards *en bloc*, the connections with the soft palate being severed with a long pair of strong curved scissors. After the removal of the palate, both antral cavities and nasal fossae were widely exposed. The bleeding was very profuse in the last stage of the operation when the palate was being detached the palatine arteries spurting vigorously. A large tampon of iodoform gauze impregnated with compound tincture of benzoin was immediately packed into the antra and palatine region and promptly arrested the hemorrhage. The lining mucosa of the right antrum was subsequently removed in its entirety. During the intraoral part of the operation the patient's head was kept low, in Rose's position. Throughout the whole procedure, which lasted over 40 minutes, the patient gave us great assistance by spitting out clots and altering the position of the head as we directed. He said that while the chisel was being used he felt the jar of the instrument, the detachment of the vomer gave him some pain, but what gave him more alarm than anything else was the sight of the blood that he spat out.

Fig. 9.—Surface anatomy of supraclavicular space, carotid and submaxillary regions to show (B.P.) Crile's method of "blocking" the brachial plexus outside of the scalenus. The oval outline indicates area of edematization in the supraclavicular fossa bisected by the line of incision. 1. Indicates mental foramina, for deep paraneural injection, surrounded by area of artificial anesthetic edema (applied in extirpation of the lower lip for carcinoma). 2. Points to submaxillary triangle which is entirely filled with the anesthetizing fluid. The dotted lines indicate line of intradermal injection for ligation in extirpating infected glands. At this point deep infiltrating injections are also made to reach the floor of the mouth, root of tongue, the lingual and inferior dental nerves which are quite accessible with long needles at this point. 3. Outline of area of anesthetic edematization for the ligation of the common carotid, external carotid and its branches, the removal of infected glands, etc. 4. Dotted line indicates line followed in making a preliminary intradermal infiltration before proceeding to the general edematization of the carotid area.

In this case the preliminary injection of morphia was of decided assistance in diminishing psychical anxiety. Fully 180 minims of Schleich's No. 1 ($\frac{1}{2}$ of 1%), and 60 minims of a 1% solution were used in the operation. After the removal of the palate the lip was still completely anesthetized and the facial (cutaneous) and intraoral (mucous) sutures were introduced without pain. The patient was very much exhausted by the ordeal he had undergone, but after taking a good drink of whiskey and a hypodermic of strychnia he sat up and said that apart from the jarring of the chisel and the excitement of the operation he had suffered comparatively little pain. The pulse was 110 and there was little shock.

In operations on the tongue, lips, cheeks, floor of

mouth and lower jaw the combined paraneural infiltration method indicated by the author in previous sections, in which large massive infiltrations with .2% eucaïn B. are made with the help of the injecting bottle, remarkably satisfactory results can be obtained. The procedure adopted by the author for the excision of the lower lip with or without extirpation of the submaxillary contents is shown in Fig. 9.

The floor of the mouth and root of tongue can be thoroughly edematized by deep infiltration with a long and fine 7 or 8 cm. needle which easily reaches the paraneural areas of the lingual and inferior dental on a level with the spine of Spix. The thorough edematization of the submaxillary fossa is also quickly obtained by the author's apparatus. The author's experience entirely confirms that of Schleich, Mehler, Briegleb and other recent German adepts in infiltration, who believe that many of the major operations on these parts can be painlessly effected by this method, only that the additional search for paraneural points which give regional control of the sensibility greatly increases the efficiency of the infiltration.

In the surgery of this region, local anesthesia has made large and permanent conquests. The neck is most favorable for the display of the infiltration method, the paraneural and intraneural methods having found comparatively few typical applications. In the neck, the lesions of the skin and its appendages and those of the supra-aponeurotic planes are everywhere submissive to cocaine or its allies. Local infiltration is most valuable in dealing with inflammatory lesions: abscesses, boils, inflamed sebaceous cysts and carbuncles of even large size. In opening deep cervical abscesses connected with submaxillary and pharyngo-tonsillar infections, in which the suppurating focus must be reached by careful dissection (Hilton-Rose), it is invaluable. In the major surgery of the neck, local infiltration finds its most brilliant applications in the anterior cervical and in the supraclavicular regions; and in the operations on the vessels in the carotid triangles, it has become the routine anesthetic in my clinics. In a cursory review of the more important operations that have been performed under local anesthesia I find most frequent references to the ligation of the carotid and its branches, the jugulars, the surgery of the larynx and trachea, the thyroid body and in the removal of large but well-defined neoplasms. Limiting myself to my personal observations, I have ligated the common carotid 7 times, and of these 5 were under cocaine. My first operation of this kind is recorded in 1889, when I ligated this vessel near its origin, between the sternal and clavicular heads of the sternomastoid, for a large idiopathic aneurysm of the bifurcation. In this case a 4% solution was used in accordance with the general ideas of the time; at present a Schleich No. 1 solution would have sufficed. I have also repeatedly exposed the common carotid in order to secure it for preventive hemostasis by passing under it a traction loop of thread (on the Rivington plan), in extensive operations on the head, neck, and especially the parotid region. I have notes of 48 ligations of the external carotid in my practice, of which 36 were performed under cocaine, several of these being double ligatures in the same subject as a preliminary to extensive operations for malignant diseases involving the tongue and floor of the mouth. In recent years I have frequently adopted Dawbarn's extirpation of the external carotid and its branches for the same purpose. The jugular vein has also been frequently exposed and

ligated under cocain. In three of my cases this vein was ligated and divided in its upper cervical portion to evacuate septic thrombi and prevent the spread of phlebitis originating in the lateral sinus from middle-ear disease.

The procedures that I have found most serviceable in the neck is indicated in Fig. 9. The lines of incision are defined by a purely intradermal infiltration with Schleich's No. 1 solution ($\frac{1}{5}$ of 1%), after which the entire field of the operation is completely edematized with a eucaïn B. 2%, introduced with the injecting apparatus. That general edematization is not necessary to obtain perfectly satisfactory results, provided the intradermal injections are carefully made, is attended by a long experience in my hands and that of others, but that complete edematization by the method described adds enormously to the effectiveness of the anesthesia and that it is a great improvement on past methods cannot be doubted.

The great advantage of operating without inhalation narcosis in the asphyxiating diseases of the larynx and trachea requiring laryngotomy and tracheotomy led to the early trial of cocain in these operations. In small children suffering from diphtheria, the restlessness and psychical disturbance of the patient contraindicates its use; here, however, intubation has practically supplanted tracheotomy altogether. But in the operations on the laryngo-tracheal passages in adults, cocain has become the routine anesthetic and its success in these cases is as fully and indisputably established as it is in the removal of an ingrowing toe-nail. I first performed tracheotomy under cocain in 1889, in relieving a laryngeal stenosis from abductor paralysis, and since that time it has become the routine anesthetic in my practice. I have had occasion to test its value in such delicate intralaryngeal operations as the extirpation of the vocal bands for paralytic stenosis, using a Trendelenburg tampon canula to prevent the entrance of blood into the lower trachea, and in the removal of foreign bodies. In these operations the reflex irritability of the mucosa must also be subdued by spraying the larynx directly with cocain solution.

One of the most convincing proofs of the great extension of cocain anesthesia in the surgery of the neck has been given by Kocher and his pupils in their numerous operations for the cure of goiter. When we consider that the statistics of operations for goiter, as furnished by the clinics of Kocher, Roux, the Reverdins, Socin, v. Bruns, Mikulicz, Burckhardt, and other surgeons who practise in the great zone of goiter infection in Europe, amount to many thousands of cases, and that since the value of cocain as an anesthetic was first established by Kocher (who alone claims a large majority of more than 1,500 goiter cases as cocain operations), local anesthesia has become a routine practice in such cases—we will realize what a large slice of surgical territory has been wrested from the domain of general anesthesia in this region alone.

With the comparatively limited opportunities for the study of thyroid diseases in our section of the country, I have performed only 7 thyroidectomies for various conditions (sarcoma, cystic and parenchymatous goiter), and in all of these cocain infiltration yielded the most satisfactory results.

In the preceding paragraphs we have endeavored to point out some of the uses of local anesthesia in the major surgery of the neck. It is only fair now to state that there still remain many conditions in which it is an

impracticable and unsatisfactory mode of anesthesia. This is particularly true of all atypical operations in which the lesions and the limits of the field of operation are ill-defined, as in multiple lymphatic tuberculosis, where the chains of infected glands are held fast to the periglandular tissues by dense adhesions. In the removal of chains of malignant lymph-nodes, the same objections hold with still greater force, and a general anesthetic becomes necessary, unless further experience justifies the extension of spinal cocainization to this region, as Tait and Caglieri have suggested. In the performance of laminectomy, in which general inhalation anesthesia is of difficult application because of the ventral decubitus of the patient, the advantages of infiltration should be seriously considered.

We have consumed much space in describing some of the topographic applications of the improved neuro-regional and infiltration methods in the extremities, head, and neck, and yet the equally important territories of the thorax and abdomen, including the hernial regions and of the special fields of genitourinary and anorectal surgery have not been even referred to. These the author has systematically considered in his monograph already referred to in which the vast utility of the methods described are exhibited in detail.

He trusts, however, that enough has been written on this paper to prove, first, that the indications for general narcosis have been vastly reduced by the development of the most recent methods of local and regional technic; and, second, that the field of application of cocain and its allies is not to be restricted to minor procedures as in the past, but that they are now proved to be reliable and potent auxiliaries in preventing the shock and secondary complications that follow after prolonged general narcosis in many of the most formidable and forbidding phases of the surgeon's major work.

Speaking from purely personal experience, I can conscientiously state that by the separate or combined application of the various methods here described the indications for the use of general (inhalation) anesthesia have greatly diminished in my practice and have steadily continued to decrease with a growing confidence in and familiarity with the new technic. I cannot claim with Schleich and others that 90% of all the operations that occur in a general surgical practice can be performed with local anesthesia, but I can safely assert that I have been able to reduce the indications for general anesthesia to at least 50 and 60% of the cases, in which, six years ago, I would have been compelled to depend upon a general anesthetic. Latterly, I have still further reduced the risks of general narcosis by availing myself of the mixed morphin cocain-chloroform anesthesia previously referred to, in which the chloroform is administered either at the end or in the beginning of the operation, and in very small quantities, with the sole object of allaying psychical excitement. Finally, I would state that while I entertain the strongest convictions on the subject of local anesthesia and never fail to avail myself of its advantages in my practice, I am not blind to its limitations and never hesitate to resort to general anesthesia when the conditions are such as to indicate or to justify their administration. Anesthesia with cocain or its allies is most often impracticable and unsatisfactory in the following conditions:

1. All operations or manipulations in which complete muscular relaxation is required to accomplish the object of the intervention; as in the reduction of fractures

and dislocations of the larger bones and joints (the hip, the shoulder, the elbow, and the knee); in relaxing ankylosed joints, spastic muscular contractures; stretching sphincters (of the rectum and bladder), etc.

2. In all extensive atypical operations on the head and trunk in which the neuro-regional method is inapplicable and the field of the operation cannot be well defined or circumscribed, as in the radical extirpation of mammary cancer by Halsted's and Meyer's methods; in the extirpation of bilateral and multiple chains of adherent lymphatics in tuberculosis of the neck, etc.

3. In all atypical operations involving prolonged and complicated maneuvers in the splanchnic cavities, especially when the organs operated upon are adherent and inflamed.

4. In all operations upon patients whose emotions are beyond the control of reason or the will, as in the violently insane, in delirious patients, in children, in hysterical and extremely timorous patients, and in all those in whom the mere consciousness of the operative act (without physical pain) is sufficient to produce great mental excitement and distress.

These are the general conditions which most frequently offer insuperable obstacles to the successful application of cocain and its allies, and yet the number and character of cases in which even the most rebellious conditions can be successfully brought under the dominion of the new technic by a patient, tactful and skilled operator is astonishing to the uninitiated. Much could be written on the qualifications that are required of the surgeon who would aim at success in the practice of local and regional anesthesia, so much depends upon the personal equation and temperament of the operator; so much upon his patience and resourcefulness in dealing with the psychical elements in his patient, that the standard of success in the practice of one operator cannot be made the rule of the majority. The technic of local analgesia in major operations is largely a personal affair; it is an intrinsic part of the operation itself and cannot be relegated to assistants, though an intelligent and tactful assistant is of inestimable value by the side of the patient, if only as aid in diverting his attention from the field of the operation—a "moral anesthetist"—as it were, to use Lillenthal's expression. It is this tax upon the operator's attention and the vigilance required to keep the inhibitory faculties of the patient under control, and the time consumed in the anesthetizing procedure that will prevent cocain and the local analgesics from gaining ascendancy in the crowded amphitheaters of popular teachers where quick and brilliant work is expected by an impatient audience. The atmosphere of such a place is not only calculated to disturb the equanimity of the patient, but is inimical to the spirit of the method itself, which commands the undivided attention of the operator.

It must be observed, however, that while these objections to cocain as an amphitheater method will always make it unpopular in large clinics it will grow in favor in all sectional teaching before small classes, and above all in the quiet and peace of private operating rooms. In every operation, the question that the conscientious operator should ask himself is, What mode of anesthesia is best suited to the condition and needs of this particular patient? Sometimes this question is not considered at all, and the operation is undertaken with a general anesthetic, simply as a matter of routine; often, however, the relative merits of ether and chloroform are

discussed, but the possible advantages of local or regional anesthesia are too rarely considered. Now, I would contend that the time has come when local anesthesia, in the broadest sense in which we have used it in this paper, deserves a higher place in the esteem of general surgeons than has been accorded to it. With Lillenthal, I would say that we have accustomed ourselves to ether and chloroform to such an extent that only in very exceptional cases do we think of the possibility of doing serious surgical work without them. Yet there are, as we have demonstrated in this paper, many major operations which can be better and more safely done with the help of local anesthetics, and it is merely the force of habit that keeps us in the old rut.

THE SPINAL SUBARACHNOID METHOD.

J. Leonard Corning, 1886—1894; A. Bier, 1899.

In previous communications (Transactions Louisiana State Medical Society, April, 1899, and *Journal American Medical Association*, June 3, 1899), I have sufficiently referred to the American origin of this method and to the great credit due to Dr. Corning for its original introduction; the subsequent events that have rapidly followed the reintroduction of the method—by Bier in April, 1899, will be sufficiently indicated by the references given in a bibliography to be published later. We are now more especially concerned with its technic and its practical value as an extension of the neuro-regional methods which we have described in the preceding pages.

We cannot regard spinal cocainization in the light of general (cerebrospinal) anesthesia because it is necessarily restricted in the limits of its territorial application and does not produce unconsciousness which is often as indispensable as analgesia. But, as a means of diminishing the indications of the general anesthetics when these or the safer but more restricted methods of neural and infiltration anesthesia are contraindicated, it is invaluable and deserves the earnest consideration that is now being given to it.

As a result of the vast amount of study, experimentation and experience that has accumulated since Quincke, of Kiel (1891), first demonstrated the utility and comparative benignity of lumbar puncture, a knowledge of the subarachnoid space and of the avenues by which it can be reached for diagnostic and therapeutic purposes had already been practically perfected before the surgical future of lumbar puncture became apparent. But even long before the possibilities of cocain medication of the cerebrospinal fluid had been recognized even by Corning, the investigations made by the earlier students of the physiologic action of cocain as the nervous centers established many data which had been practically forgotten, but which, in the light of the present experience, are interesting and instructive. This is particularly true of the work of Mosso (1890), Aducco (1889), F. Franck (1892), who specially studied the effect of topical applications of cocain upon the medulla oblongata. But to Sicard (May, 1899) we are specially indebted for the most satisfactory experimental and comparative study of the toxic phenomena produced by cocain when introduced into the subarachnoid space by the intracranial route as well as by spinal puncture. The far greater gravity and rapidity with which toxic phenomena are produced when the action of cocain is extended to the cerebral centers as shown by these researches, are well worthy of reflection and throw much light upon the

grave toxic symptoms which have already been frequently recorded by operators who have exceeded the dose prescribed by Bier and Tuffier. We shall not attempt to discuss the physiologic phases of the method on this occasion, but will limit ourselves to its purely practical surgical features as they have presented themselves to me in the course of my personal experience.

The subarachnoid space is accessible by several routes:

FIG. 10.—Method of puncture for spinal drainage: (A) Quinke's method; (B) Marfan's; (C) Chipault's; (D) Tuffier's.—Modified from Chipault.

(1) By trephining the skull; (2) the atlantooccipital route (followed by Magendie in demonstrating the constant presence of the cerebrospinal fluid); (3) the dorsal route, with or without laminectomy; (4) the sacrolumbar route; (5) through the central spinal canal; (6) the cervical route. For purposes of regional anesthesia, the intervertebral spaces are alone utilized, as it is only from the first lumbar vertebra downward that injury to the spinal cord can be avoided. The other routes referred to have been utilized almost exclusively for experimental purposes or for therapeutic injections into the subarachnoid space for other than purely surgical conditions. Recently Tait and Cagliari of San Francisco, in a valuable and interesting contribution on the subject (*Jour. Am. Med. Assoc.*, July 7, 1900) have stated that in their experience the sixth cervical space is a sure and extremely easy avenue in the human subject, and have availed themselves of it in three cases for purposes of surgical analgesia without apparent injury to the cord or untoward result. They believe that the spinal cord, like the brain, is tolerant of trauma, and do not fear the possibility of injuring it permanently with a fine needle while introducing the cocain solution. Notwithstanding their confidence and the repeated successes they have obtained, I cannot consider it a safe route to the spinal canal, and cannot recommend it in the regular practice of spinal anesthesia. In addition to the risk of traumatism and hemorrhage there is the additional greater liability of inducing serious toxic phenomena, owing to the greater proximity of the seat of injection to the medulla oblongata which is very susceptible to the paralyzing influence of even small doses of the drug.

¹ Mosso found that 2 drops of a 10% cocain solution dropped carefully into the floor of the ventricle of rabbits caused an almost immediate arrest of the respiration and death. Aduco repeatedly demonstrated in dogs that from .05 to .10 cgm. of the drug, when dropped into the fourth ventricle, promptly arrested its reflex excitability with failure of the respiration and death. He compares the action of cocain to direct section of the organ with the knife, so prompt and certain is its paralyzing effects (*vide U. Mosso, l. c.*).

After having experienced some difficulty in reaching the spinal canal in my first cases of spinal cocainization in which I had resorted to Quinke's puncture as recommended by Bier, I investigated the subject on the cadaver and arrived at the conclusion that the space between the fourth and fifth lumbar vertebrae is the best suited for puncture and injection. This, however, as I have since found out, is not always the best point, and have in one case been compelled after failure to enter at the fourth intervertebral space to try Chipault's sacrolumbar foramen between last lumbar and sacrum, with success. (Fig. 10 showing different methods.) In another case, a very fat patient, I only succeeded in the second intervertebral space. Fortunately all the spaces, from the second lumbar to the lumbosacral, are available and the injections can be safely made in any of these. The dorsal route also is accessible as high as the sixth space, as shown by Sicard, Tait and Cagliari; but these are objectionable for many reasons and preference should always be given to the lumbar spaces. The largest of these is the sacrolumbar space, but the space between the fourth and fifth lumbar recommended and adopted by Tuffier, is, as a rule, the most easily identified by surface landmarks. The average size of the interlamellar spaces through which the needle enters the spinal canal in the lumbar region varies from 18 to 20 mm. in transverse and from 10 to 15 mm. in vertical diameter (Quinke, Chipault) and the point of a No. 10 or 15 French conical urethral bougie could be introduced into the space without difficulty in an adult. The distance to be traversed by the needle varies from 7 to 8 cm., and much less in thin adults. The mode of procedure adopted in my practice has been practically identical

FIG. 11.—THE SPINAL SUBARACHNOID METHOD OF COCAINIZATION.—The patient is seated on the edge of the operating table. The exact position of the iliac crests having been previously determined, the spinous process corresponding to a transverse line drawn across the spine, on a level with the highest points of the crests of the ilia, is held by the left index. The right hand of the operator holds the needle which is directed forward and towards the middle line from a point 1 cm. ($\frac{3}{8}$ of an inch) to the right of the spine.—Tuffier, *Sem. Med.*, May 16, 1900.

with that recommended by Tuffier. In all my 9 cases the sitting posture has been adopted and the directions given by him for the identification of the fourth inter-

space were followed with some differences in the mode of exploring the canal before I had read his communication of May 15, 1900, *Semaine Medicale*, in which he fully detailed his procedure. His description of the procedure is excellent and cannot be made more graphic. The patient is seated on a table with his back to the operator. The hands resting on the thighs support the trunk. The lumbar region is thoroughly prepared with the

FIG. 12.—THE SPINAL SUBARACHNOID METHOD.—The dotted line crosses the top of the fourth lumbar spine on a level with the highest points of the iliac crests.—Tuffier.

usual antiseptic care, including a thorough scrub with alcohol, followed by lysol or bichlorid. The trunk is held nearly upright, with the spine as straight as possible. The highest points of the iliac crests are now identified posteriorly (a very difficult matter in obese patients), and a horizontal line connecting these two points is drawn across the spine. It will be found that the tip of the fourth lumbar spine touches this line. In fat subjects it is often very difficult to identify the spine and its situation can only be approximated. When it can be clearly identified, as in the majority of patients, it will usually be an easy matter to penetrate into the canal if the canula is thrust at a point just below and to the outer side of the junction of this line with the fourth spine. The skin at this point and for a quarter of an inch to the right of the median line is infiltrated with a few drops of Schleich's No. 1 or No. 2 cocain solution.

I prefer to use a fine but long hypodermic needle which infiltrates the entire tract, to be followed by the injecting canula, and while doing so explore the way to the interlamellar space. This procedure is of value in stout subjects in whom the spinous process is not accurately identified and in whom an error in the recognition of the spine would lead to an additional and unnecessary puncture. The left index is now held as a guide touching the fourth lumbar spine, and the patient is told to lean forward and curve his back ("searching posture") in order to increase the dimensions of the fourth intervertebral space; $\frac{5}{8}$ in. is gained in the vertical diameter by this procedure (Tuffier). The canula of the injecting syringe, with a small (30 minims) empty hypodermic syringe attached, is held in the right hand and is made to penetrate into the skin about 1 cm. ($\frac{1}{4}$ in.)

to the right and immediately below the fourth lumbar spine. The canula is thrust slowly and steadily forward and towards the median line into the interspinous space for a distance usually of $2\frac{1}{2}$ to 3 inches (about 6.50 to 7 cm.). If the needle has penetrated the subarachnoid space, a diminished resistance is felt which is unmistakable to the experienced operator, and if the piston of the syringe is drawn a perfectly clear watery fluid—the cerebrospinal fluid—will immediately flow into the chamber and the evidence will be conclusive that the subarachnoid space has been tapped. The moment the presence of the fluid is established—and a few drops of the fluid are sufficient—the exploring syringe is disconnected and another syringe already charged with the anesthetic solution is attached and the anesthetic is slowly injected. Care must be exercised to avoid any unnecessary loss of cerebrospinal fluid, as serious accidents have followed excessive drainage in several cases. Bier himself was made quite ill from this cause when the method was tried on himself by his assistant, Hildebrand. This accident is easily avoided by using syringes that are fitted without screw tips.

Special attention must be given to the exact dose of cocain injected and to the aseptic preparation of the solution. Bier in first cases operated from August 16, 1898, to April, 1899, used 2 cc. of a 1% solution. He never exceeded 15 mgm. or $1\frac{1}{2}$ cgm. Tuffier, whose experience with the method is greater than that of any other operator (130 cases up to September, 1900), invariably uses a 2% solution of cocain, of which he injects 1 cc. (15 minims.) The total dose, he insists very correctly, should never exceed 15 mgm. or $1\frac{1}{2}$ cgm. In my own practice I began by using 1 cc. of a 1% solution of eucain B; after the flow of cerebrospinal fluid had been clearly demonstrated; the needle, with the syringe attached, was left *in situ* pending observa-

FIG. 13.—THE SPINAL SUBARACHNOID METHOD.—The needle penetrates into the spinal subarachnoid space below the fourth lumbar spine. The termination of the spinal cord on a level with the lower border of the first lumbar vertebra is shown in the diagram. The needle entering in the middle line does not touch the fibers of the cauda equina, which are spread in two lateral bundles.—Tuffier.

tion of the anesthetic phenomena; after 10 minutes' delay, as there was no anesthetic effect, another cubic centimeter was injected, and the canula was with-

drawn. Absolutely no effect followed. It would appear from this experience that eucain B. in the same doses as cocain is absolutely inefficient. Tait and Cagliari state, however, that in the lower animals the effects seem to differ but little from those of cocain. I am convinced that to be as effective as cocain the dose will have to be increased and it would be interesting to observe the results of further experimentation in this direction. After my first experience, I used a cocain solution, 1%, sterilized by heat (fractional method). When using the 1% solution I invariably injected 1 ccm. first and waited for the result, leaving the needle and syringe *in situ*; if the effects were not pronounced in 8 or 10 minutes, another cubic centimeter was administered, when as a rule the result was satisfactory. In the last three cases, however, I have become so confident of the effect that can be obtained with 1 cgm. of the drug that I now inject and withdraw the canula at once and seal the puncture with cotton and flexible collodion. In preparing the solution in these last cases the method adopted was as follows: Five tablets, each containing $\frac{1}{6}$ grain of cocain hydrochlorate; $\frac{1}{40}$ grain morphin hydrochlorate; $\frac{1}{2}$ grain sodium chlorid, were dropped into 100 minims of hot distilled water and dissolved. The solution was again sterilized by the fractional method. Twenty minims of this solution represent $\frac{1}{6}$ of a grain of cocain, $\frac{1}{10}$ of a grain of morphin and $\frac{1}{2}$ of a grain of sodium chlorid. The syringe, which contains 30 minims, was filled with the solution and 22 minims were injected; the excess of two minims is allowed for waste. The solution should always be used warm, about 90°–100° F. The effects following the injection of this mixed cocain-morphin-saline solution were so satisfactory that in future I shall continue to use this combination. The tablets used were those sold for the ready preparation of Schleich solution No. 1 by several well-known and reliable manufacturers. The ease with which a reliable and accurate anesthetic solution can be prepared with the manufactured tablets is one of their chief recommendations. The combination of cocain with morphin and other drugs has been tried by several observers with contradictory results. The reasons why I ventured to try the addition of morphin in small doses ($\frac{1}{40}$ grain) were (1) that I hoped to intensify and prolong the anesthetic effect of the cocain without adding to its toxic qualities, and (2) because I expected that the morphia through its sedative effects upon the cortex would tend to diminish the great mental distress and excitement that is so frequently exhibited by patients before and during the course of even the most painless operations.

That the addition of morphin will prevent the development of the postanesthetic phenomena I do not believe; but that the addition of a very small dose of morphin does not add to the dangers of the method and has the same sedative effect on the mind that it usually exercises when administered in larger doses by the subcutaneous route, I do not doubt.

Another point of importance is the necessity of providing a properly sterilized outfit. This can be usually improvised anywhere with a good antitoxin syringe. I have used the ordinary Walcher's solid piston metal syringe and needle for this purpose; but have used more often a long fine canulated needle, about 7 cm. long (about No. 22 Dieulafoy), that is provided with ordinary exploring aspirators. I have adapted it to two ordinary hypodermic syringes, 30 minims capacity, which could be used separately to explore and inject.

Bier, Tuffier, and the majority of operators first introduce the canulated needle without other attachment, and watch for the escape of the cerebrospinal fluid before injecting. Schiasi, of Bologna, fearing the effects of unnecessary loss of cerebrospinal fluid, leaves the injecting syringe attached from the start and trusts simply to the characteristic sensation which is experienced in penetrating the canal, for guidance. That this sensation is fallacious I know by repeated experience. In fact, if there is anything that is essential for the successful performance of subarachnoid puncture, it is the strict and unswerving observance of Tuffier's golden rule, "never to inject the cocain solution until the cerebrospinal fluid is distinctly recognized." This is the only infallible proof of penetration into the canal, all other signs are misleading, unless the operator is

FIG. 14.

FIG. 15.

FIG. 14.—Tuffier's iridoplatinum needle. Actual size, 9 cm. long. External diameter of, 1.1 mm.; internal of, 0.8 mm. The sharp but short point is important.

willing to wait for the anesthesia as a test. But, returning to the needle itself, we find that using comparatively short 7 cm. canulated needles, it is not satisfactory to manipulate them unless they have the syringe attached, as this gives a firm hold. With Tuffier's long iridoplatinum needle, this disadvantage is overcome, and the syringe is not needed as a holder to give a firm grasp to the operator's fingers in directing the canula. The accompanying cuts illustrate the regular Tuffier canula made for me by the Messrs. Tiemann & Co. (See Fig. 14.) The syringe is an ordinary metallic hypodermic with glass barrel which will hold 30 minims (2 cm.) properly graduated. The plunger is made of asbestos packing,

and the whole can be thoroughly sterilized. An admirable aseptic glass Parvaz syringe (see Fig. 15) is also manufactured for this purpose by the Messrs. Kny, Scheerer Co. It is modelled after the original Tuffier syringe and is provided with improved aseptic fiber packing, which can be readily sterilized by boiling. The needle shown in this cut is only 5 cm. long; the regular Tuffier needle, 9 cm. long, is furnished with the needle by the manufacturers. It is important that all needles used for spinal cocainization should be cut sharp, but *short* at the point, as a long, very oblique bevel-point may penetrate the canal and yet allow the contents to escape in the extradural space.

We have already incidentally referred to some of the difficulties and accidents which may accompany the procedure. These are chiefly centered in the not infrequent inability of the operator to find the interlamellar opening. These have been commented upon by almost all observers who have had experience in the practice of lumbar puncture. They are most frequent in very muscular and obese subjects in whom the spines and other landmarks are not easily felt. Tuffier and his pupil, Cadol, have noticed the special difficulties presented by subjects with deformed spines. An interesting case of this kind has been recently reported by S. Coelho, of Lisbon, in which repeated attempts at penetration failed totally because of the cicatricial rigidity of the spine caused originally by an abscess. I have more than once been compelled to repeat the punctures four or five times before reaching the cerebrospinal fluid. If the needle is directed too obliquely (laterally) it will strike a lamina; if pushed too far forward into the canal it will bury itself into the body of the vertebra and only a few drops of blood will flow. It is necessary to direct the point strictly towards the median line in the center of the interspinous space, only keeping closer to the upper spine than to the lower. Then all further attempts at penetration should cease the moment the characteristic sensation of diminished resistance is felt.

As to the immediate accidents of the operation there are, as a rule, none. Nevertheless Gumprecht (*Deutsche med. Woch.*, xxvi, June 14, 1900) has collected 17 cases from the clinics of Quincke, Fürbringer, Lenhart, Lichtheisen, Wilms, Krönig, Bull, and his own, in which death has followed quickly after lumbar puncture for exploratory purposes, and in which the fatal termination could be attributed to no other cause than this apparently trivial operation. It must be noted, however, in justice to the method, that these punctures were made in patients suffering from very serious affections of the central nervous system and meninges and that, in at least several, the sudden deaths may have been due to other accidental causes. Symptoms referable to injury of the fibers of the cauda equina have been referred to by Sicard and Cadol. It is well to remember the greater possibility of hemorrhage in arteriosclerotic subjects. Heunberg has recently reported (January 19, 1900, Cadol) a case in which an intradural and medullary hemorrhage followed an injury to the veins which accompany the filum terminale. In this patient an exploratory lumbar puncture had been made 24 hours before death and 25 cm. of cerebrospinal fluid containing numerous bacilli had been removed. This was evidently a very exceptional case and the injury done to the cauda is accounted for by the tubercular meningeal adhesions which were found at the autopsy. In ordinary, normal conditions of the spinal cord, injury to the cauda equina and filum are almost impossible, as Quincke has shown that owing to

the mobility of the caudal nerve-fibers in the fluid they are easily pushed aside by the needle; hence the advantage of using a needle that is not too pointed.

From this it is evident that the mere act of puncturing the spinal subarachnoid space is not altogether free from risk. On the other hand, when we consider that many thousands of punctures alone, and now several hundreds, probably more than a thousand spinal cocainizations have been made for surgical purposes throughout the world and no serious accidents have been reported as a result of the operative procedure itself, it is obvious that the operation is, in normal condition of the spine, and in the hands of a careful operator, practically free from danger.

By far the greater danger lies in the effect of the anesthetic drug itself. That the toxic effects of the cocain injected may give rise to serious, alarming and even fatal manifestations cannot be doubted by any one who will read the detached reports of the many cases that have appeared in the medical press in the course of the last twelve months. These bad effects may show themselves immediately during the acme of the anesthetic period, but more constantly in the post-anesthetic stage and 12 hours after the injection. In justice to the method it must be said, as Tuffier has pointed out, that they are observed whenever more than one or two centigrams of cocain have been injected. The observations of the Roumanian surgeons, who have had a remarkably large experience with spinal cocainization, especially those of Racoviceanu-Pitesci, who has operated on 125 patients by this method and of Severeanu, also of Bucharest (70 cases up to last August), are worthy of special attention in this connection. Their opinions are extremely conservative and far from reassuring as to the ultimate fate of the method—at least as a routine procedure. Racoviceanu-Pitesci whose experience is almost as large as that of Tuffier, said at the important discussion that took place at the recent International Congress, August 8-10, in Paris, that he knew of 2 deaths that had occurred in Roumania as a result of spinal cocainization. In 80 of his cases he had observed light or moderate forms of intoxication which had persisted for 4 or 5 days. In 3 cases he had observed grave and alarming accidents which had compelled a resort to artificial respiration, hypodermic injections of ether, caffeine, and other measures. In other cases reported by Severeanu, this operator had observed a condition of general exhaustion and prostration which had lasted from one to two days and had given cause for very serious apprehension.

In reading the detailed observations of these cases, especially those published in the *Roumania Medica*, of February 15, 1900, by Stefan Alessiu, and in the *Spitalul*, of March 15, 1900, by C. N. Poenaru, both internes in the services of Pitesci and Severeanu, one is struck by the frequency with which serious symptoms of collapse, vomiting, pallor, cold sweats with respiratory and circulatory failure with total relaxation of the sphincters and involuntary evacuation of feces, necessitating the most energetic restorative measures in the course of the operation—are observed in some of the worse cases, in several of which only 2 cgm. of cocain ($\frac{2}{3}$ gr.) had been injected. It is not surprising therefore that all of the Roumanian surgeons should be cautious in their expressions of opinion and that not one of these should believe that the spinal subarachnoid method will supplant the general anesthetics except in special conditions. The experience of the Roumanian surgeons distinctly sustains

Prof. Bier in the very conservative and guarded attitude that he has maintained since he first introduced the method for surgical purposes in 1898. In a letter to M. Cadol, last January (1900), and in his recent paper (*Munch. med. Woch.*, 1900, xxxvi, p. 1226), he holds that the problem is not to use cocain in the manner which he first described and for which he predicts no great future, but to devise means of rendering cocain harmless and to prevent its unpleasant and after-effects, or to discover some nontoxic substances. He very rightly condemns the doses of 4 and 5 cgm. which have been frequently used, as dangerous, and, with Tuffier, says that the dose should not exceed 15 mgm. or $1\frac{1}{2}$ cgm.

Tuffier himself, the brilliant propagandist of the method, admits that in 125 cases he had 5 deaths, 4 of which could not be referred to the anesthetic; the fifth, however, died with the symptoms of asphyxia. The autopsy showed mitral insufficiency and two fresh lung-emboli.

That overdosing is, however, the great source of danger is evident, and the symptoms of circulatory and respiratory failure that have been observed remarkably bear out the early experimental demonstrations of the evil effects of even small quantities of cocain in the medulla made by Aducco and Mosso in 1889 and 1890.

On the other hand, in spite of all these very serious accusations and proofs of danger it is curious that a complete immunity from the evil, or even the ordinary physiologic effects of cocain should be exhibited by many persons. Thoroughly authentic cases of this kind have been reported by Racoviceanu, his pupil Alessiu, Pousson, and Chavanaz and Coelho. In these cases the writers state that the puncture was demonstrative, the cerebrospinal fluid being recognized and yet injections of 2 cgm. were injected with very slight or insufficient effect. In a case related by Coelho the patient was an alcoholic and proved almost as rebellious to chloroform as to cocain, and he asks the question whether chronic alcoholism might not have some influence in neutralizing the effect of the drug. These recalcitrant and rebellious cases are accounted for by Cadol, Tuffier, and others by failure to apply an active preparation of the alkaloid, or by defective technic, and this is probably true of some, but the instances are too numerous to justify this as an adequate explanation.

My personal experience with spinal cocaineization began November 10, 1899, and has been limited to 9 cases. I have had numerous opportunities to apply the method, but I have made it a rule not to resort to it unless there were positive reasons to justify it. The history of these cases entirely confirms all the observations previously made on this subject. They confirm all that has been said in favor of the procedure, and of the intensity and duration of the anesthesia, and show very little against it. I have never exceeded 2 cgm. and have obtained my most satisfactory results in major operations with $\frac{1}{2}$ grain of cocain combined with $\frac{1}{10}$ grain of morphia dissolved in saline solution (Schleich formula). The conditions in which it was employed were 2 operations for hemorrhoids, one perineal section for vesical drainage, one vaginal resection for malignant disease, one perineal cystotomy combined with the Bottini operation, one amputation of the thigh after an extensive exploration of a tubercular femur and knee, an attempt at sequestrotomy under eucain that failed completely after successful injection of 2 cc. of a 1% solution of eucain B., two earlier cases of rectal exploration and dilation for

malignant stenosis which were only partial successes in consequence of too weak injections ($\frac{1}{2}$ cgm. of cocain).

All of these cases were exempt from toxic or serious symptoms during the operative or anesthetic period. In at least four the most perceptible effect was a greater mental stimulation, shown by abnormal loquacity and cheerfulness. In 3 the symptoms were absolutely negative; in 2 there was vomiting at the end of the anesthesia. In several, the pulse was markedly accelerated, probably from excitement, but in the majority it was normal throughout the operation. In only 3 did we deem it necessary to stimulate with a toddy or a hypodermic of strychnia and atropia. In these cases there was some pallor and sweating, but without anxiety. The postoperative phenomena came on from 5 to 12 hours after the injection, and these were chiefly headache, which, in one case, persisted for 10 days. Vomiting was never observed more than two or three times in the worse case. The temperature rose in my second case (December 11, 1899) to $103\frac{1}{2}$ F., but it gradually subsided in 24 hours. In this case there was also very intense and persistent occipital headache. In this instance (a mulatto) the anesthesia was most remarkable. It came on promptly after the injection of 2 cc. of a 1% solution; it spread rapidly upwards from the lower extremities and pelvis to the thorax, arms, and neck. The anesthesia was so complete that any cutting operation could have been painlessly performed in the upper extremities. The patient felt absolutely no inconvenience after the ligation and excision of the hemorrhoids, and insisted upon walking back to his ward. On the other hand, the postanesthetic symptoms referred to were very intense, showing that these reactionary symptoms are often proportional to the intensity and duration of the anesthesia. In all the other eight cases the temperature never exceeded $100\frac{1}{2}$, and in four was absolutely normal. The most constant and unfailing symptom was the headache, and this was relieved by the use of phenacetin and caffeine, and other coal-tar derivatives of the same kind. In a case—that of a physician upon whom a perineal section with the Bottini operation was performed—there persisted a feeling of tingling and numbness about the feet that made him uncomfortable for more than 12 days after.

It will be seen from this limited experience and synoptical presentation of the facts that I have no very serious complaint to make against the method, but this I attribute largely to the extreme caution with which I have applied it.

Judging purely from my personal experience, I would limit the indications for its applications at the present moment:

1. To adults, and to reasonable persons who have good self-control, thereby excluding children, hysterical patients, and the insane.
2. To patients in whom the methods of local or regional anesthesia are inapplicable.
3. To patients suffering from emphysema, advanced asthma, chronic bronchitis, and other respiratory affections in whom a general inhalation anesthetic is absolutely contraindicated; in advanced cardiac cases with degenerative lesions, I would fear the possible depressing effects of the injection and excitement on the circulation.
4. In the majority of cases in which the painful part of the operation is not likely to be prolonged beyond one hour and a half, as I would be averse, in the present state of our knowledge, to repeat a second cocaineization or to increase the total dose of the cocain to more than 2 cgm., especially in exhausted subjects.

The danger of repeating the intradural injections to prolong the anesthesia is also one of the objections to the use of the method in ordinary labor. But its advantages in instrumental cases, as shown by the successful experiences of Dupaigne, of Louviciennes, France, (who, according to Tuffier, first applied the subarachnoid method in labor, January, 1900), and of Bumm and Kreis, of Basle; of Doleris and Malartic, of Paris; and Marx, of New York, cannot be doubted, especially in nephritic patients.

COCAIN ANALGESIA FROM SUBARACHNOID SPINAL INJECTION, WITH A REPORT OF FORTY-FOUR CASES, TOGETHER WITH A REPORT OF A CASE IN WHICH ANTIPYRIN WAS USED.

By GEORGE RYERSON FOWLER, M.D.,
of New York.

Professor of Surgery in the New York Polyclinic; Surgeon to the Methodist Episcopal Hospital; Surgeon-in-Chief to the Brooklyn Hospital; Senior Surgeon to the German Hospital.

THE employment of subarachnoid injections of a solution of cocaine for the purpose of producing analgesia for surgical purposes has been recently brought into prominence by a report of 125 cases by Tuffier, at the Thirteenth International Congress at Paris; of 70 cases by Severeanu, of Bucharest; and of 125 cases by Racoviceanu-Pitesci, also of Bucharest. The method however, was not original with either of these surgeons. Its first application to surgical practice in Europe is justly credited to Bier, of Kiel. Dr. Leonard Corning, of New York, however, first called attention to it in his articles upon the subject of cocaine in the *New York Medical Journal* in 1885 and 1888, and subsequently in his book upon "Pain," published in 1894, in which both the method and its technic were developed.

Whether or not the surgical application of the method originated by Corning will rank as an epoch-making event in our art will depend entirely upon future experiences with the effects of the drug as applied in this manner. If the estimate which some surgeons who have used it are disposed to place upon it is upheld by its further employment, a field of usefulness will have been opened up by its introduction; although, until some method is developed whereby it may be applied to operations upon the upper portions of the trunk, as well as to the upper extremities and head, it can scarcely be hoped that it will replace ether and chloroform.

My attention was first called to it by Bier's work, but I had been given to understand that he had abandoned the method after a trial of it upon his own person. Like many others, however, who had probably been restrained from trying the method by this circumstance, I did not take into account the susceptibility of some individuals to the mental depressing effects of cocaine. Subsequently, however, I recalled the fact that one of my own former assistants, a surgeon of exceptional ability and evenly balanced mind, was for a time prevented from taking part in operations in which the agent was used after having it used upon himself in the ordinary manner for incising a simple phlegmon. While still debating the feasibility of extending Bier's experiences with the method the matter became the subject of renewed interest to me by an invitation to witness a hysterectomy by Tuffier in which subarachnoid cocaine was to be employed. Unfortunately, a misapprehension as to the time and place for the operation prevented me from attending. Tuffier's reports of his

cases, however, impelled me to give the method a trial upon the first opportunity. The following is a brief resume of the cases in my service up to the present time that have been subjected to the method:

CASE 1.—The patient was a male, aged 23, entered at the Methodist Episcopal Hospital, September 8, 1900, for excision of hemorrhoids; 15 minims of a 2% solution of cocaine muriate were injected. Complete analgesia followed in 3 minutes, extending to tenth rib. Somewhat greater difficulty was experienced in dilating the sphincter ani as compared with ether or chloroform narcosis, owing to the absence of muscular paralysis. Patient vomited at end of 19 minutes. Analgesia lasted 50 minutes. There were no after-effects.

CASE 2.—The patient was at the German Hospital, September 12, a female, aged 40. The operation was abdominal section for appendicitis. Patient was placed in the semiprone or Sim's position, and 20 minims of a 2% solution injected. Analgesia was established to the fourth rib in 5 minutes. The patient complained of pain when the inflamed peritoneum was handled, but of no other incidents during analgesia, which lasted 65 minutes. At 8 P.M., or about 10 hours after the operation, the patient suffered what seemed to be an attack of angina pectoris. Her condition seemed alarming and her husband was summoned, who stated that she frequently had such "spells." Under stimulating applications and spartein she rallied. Her recovery thereafter was uneventful.

CASE 3.—The case was at the German Hospital, September 12, 1900, for tenosynovitis of the inner hamstring tendon; 5 minims of 2% solution were injected without analgesia in 15 minutes. A second injection of 5 minims was then given; analgesia to the tenth rib followed in 8 minutes; 6 minutes after the last injection the patient vomited; 10 minutes thereafter there occurred both urination and defecation involuntarily. Analgesia lasted 45 minutes. There were no after-effects.

CASE 4.—Was of a female, 39 years old, at the German Hospital, September 12, for ligature of both internal saphenous veins for varicose veins; 15 minims of a 2% solution were injected. Analgesia was established to the fourth rib in 5 minutes. She vomited after 10 minutes, and had involuntary defecation after 15 minutes. This was repeated twice during the operation. Analgesia lasted 55 minutes. There were no after-effects.

CASE 5.—The case was one of vaginal hysterectomy, at the Brooklyn Hospital, September 13, 1900. The first puncture withdrew a small quantity of somewhat viscid and turbid fluid. At the end of 25 minutes, following an injection of 20 minims of a 2% solution, there was no analgesia, when another puncture was made, and indubitable cerebrospinal fluid was obtained, when an injection of 25 minims of a 2% solution was made; analgesia followed in 4 minutes to the axillae. Sensations of touch were present throughout the operation. The pupils were unaffected, the pulse was 96, and the respirations rose at times to 32. Seven minims of Magendie's solution were given. She was nauseated several times during the operation. The patient developed an hysterical attack after removal to the ward. Her friends stated that she suffered from such attacks frequently.

CASE 6.—The patient was a female, aged 40, at the Methodist Episcopal Hospital, September 13, 1900, for anterior colporrhaphy and perineorrhaphy; 12 minims of a 2% solution of cocaine muriate were injected, followed by analgesia up to the free border of the ribs in 3 minutes; sensation returned in 27 minutes, and 3 drams of chloroform were administered to complete the operation, which lasted 45 minutes. Patient became nauseated 5½ hours and vomited 6½ hours after operation. There were no other complications.

CASE 7.—The patient was a male, aged 42, at the German Hospital, September 14, 1900, for excision of hemorrhoids; 15 minims of a 2% solution were injected, with analgesia to the level of the umbilicus established in 3 minutes. The sensation commenced to return in 51 minutes. There were no apparent effects other than the analgesia either during or following the operation. During the night he complained of painful contractions of the fingers of the right hand. Patient is suffering from phthisis pulmonalis.

CASE 8.—The patient was a male, aged 38, at the New York Polyclinic, September 18, 1900; an alcoholic and syphilitic,

with varicose veins of both legs. Cerebrospinal fluid was withdrawn, small in quantity and turbid; 20 minims of a 2% solution were injected, with no analgesia at the end of 15 minutes; 30 minims more of the same solution were then injected, with no result after 20 minutes, and no effects. The patient returned to the ward, with no after-effects.

CASE 9.—At the Methodist Episcopal Hospital, on September 18, 1900, a male, aged 32, was entered for excision of hemorrhoids; 17 minims of a 2% solution were injected, with complete analgesia up to the free border of the ribs in 2 minutes. Operation was completed in 15 minutes; at the end of the operation the patient was allowed to stand upon his feet. He was quite unsteady, and could not support himself. He had slight nausea and vertigo at the time, and vomited on lying down. There was no pain and no after-effects.

CASE 10.—Was entered at the Brooklyn Hospital, September 18, 1900, a female, aged 28, for curettage, trachelorrhaphy, and perineorrhaphy; 20 minims of a 2% solution were injected; 19 minutes were required to produce analgesia, which extended to the level of the clavicle, and included the upper extremities. Vomiting took place before analgesia was established. She was restless only when nauseated, and said her fingers "felt like pins and needles." The pulse varied from 72 to 120; 8 hours after the injection it was 67. Headache commenced 3 hours after injection, and lasted until midnight. Chilly sensations were complained of at the same time. There were no further after-effects.

CASE 11.—A female, aged 30, was entered at the Brooklyn Hospital, September 18, 1900, for operation for the radical cure of inguinal hernia; 20 minims of a 2% solution were injected. Analgesia followed in 6 minutes, extending to the level of the fourth rib; the pulse averaged 92 and respiration 34 during the operation; 12 hours after the operation she developed what appeared to be a hysterical attack. The head of the bed was elevated and she was given 7 minims of Magendie's solution hypodermically, after which she quieted down, and with the exception of a headache, which subsided in a short time, she slept well during the night. There were no further after-effects.

CASE 12.—A female, aged 19, was entered at the Brooklyn Hospital, September 19, 1900, for curettage and trachelorrhaphy; 20 minims of a 2% solution were injected at 10.48. Analgesia was established at 10.55 (7 minutes), which extended to the level of the fourth rib. There was no nausea or vomiting. The pulse ranged from 80 to 88; respiration from 20 to 24; 3 hours after injection there was headache and chill; 4 hours after the temperature rose to 101.6° F.; at 8 the next morning it had fallen to 98°, morphin $\frac{1}{4}$ gr. and 1 ounce of whisky were given for chill and headache. There were no further after-effects.

CASE 13.—This patient was a female, aged 33, at the Brooklyn Hospital, September 20, 1900, for curettage and trachelorrhaphy; 20 minims of a 2% solution were injected at 10.40. Analgesia extended to the fourth rib in 10 minutes. The pulse before injection was 96; at 10.50 it was 144; at 11.05 it was 152. Respiration ranged from 20 to 36. At 11.15 patient vomited; 12 hours after injection, the temperature rose to 101° F.; 8 hours after the injection morphin $\frac{1}{4}$ gr. was given, after which the pulse dropped to 80, and headache, which had been in existence for 8 hours, subsided. There were no further after-effects.

CASE 14.—The patient was a female, aged 18, at the Brooklyn Hospital, September 20, 1900, for excision of suppurating vulvovaginal gland (the patient was 3 months pregnant); 20 minims of a 2% solution were injected at 11.27, and analgesia to the level of the fourth rib was established in 4 minutes; 4 minutes thereafter she vomited. The pulse just before the injection was 120; by 4 in the afternoon it was 76. At this time she complained of severe pain in the head and eyes, and of stiff neck. Given 2 grains of caffein citrate hypodermically, she passed a comfortable night, and the next morning seemed as well as ever.

CASE 15.—A male, 40 years old, was entered at the Methodist Episcopal Hospital, September 22, for fracture of the patella. Puncture procured but a small quantity of turbid fluid. The needle became blocked with blood-clot twice, necessitating three punctures. The first of these was made in the third interspace, the second in the fourth, and the third in the second. These were made at intervals of 20 minutes, 50 minims of a 2% solution of cocain being used. There were no discernible effects of the drug. The patient was re-

turned to the ward, and was operated upon 2 days afterward under ether narcosis.

CASE 16.—The patient was a female, aged 22, at the German Hospital, September 24, for tubercular arthritis of the knee; 20 minims of a 2% solution were injected, only a small quantity of fluid withdrawn, and this was turbid. There was no analgesia in 36 minutes. Chloroform narcosis was established with unusual ease, and operation of incision and drainage of the knee-joint was carried out. There were no unpleasant after-effects attributable to the cocain.

CASE 17.—A man, aged 50, was entered at the Methodist Episcopal Hospital, September 22, 1900, for excision of hemorrhoids; 20 minims of a 2% solution were injected. Analgesia was complete to the tenth rib in 3 minutes, with no nausea or vertigo. Analgesia was still complete at the end of 1 hour and 35 minutes. Sensation gradually returned and was completely normal at the end of 2 hours and 50 minutes. There were no after-effects.

CASE 18.—The operation was for radical cure of inguinal hernia, in a male, aged 60, at the Brooklyn Hospital, September 25, 1900; 13 minims of a 2% solution were injected at 10.48, and analgesia extending to the fifth rib established in 7 minutes; at 11.03 he vomited, was restless when nauseated, and excited when he heard orders given in passing instruments, etc. When the spermatic cord was handled he complained, mildly of pain. He broke out in a cold perspiration. Pulse before injection was 112; 20 minutes following the injection it rose to 140, and then fell in an hour to 80, from which time it varied between 120 and 80 until the following morning. During the same time the respirations varied from 28 to 34. Headache came on 4 hours after the injection, and was relieved by 2 grains of caffein citrate.

CASE 19.—The operation was an abdominal hysterectomy at the Brooklyn Hospital, on September 25, 1900; 20 minims of a 2% solution were injected at 11.33 A.M.; analgesia to the third rib was established in 2 minutes. The patient vomited at 12.15. Operation was completed at 12.45. The patient was very nervous and frightened in the operating room and her pulse was 140 before the injection. It dropped to 105 10 minutes before the completion of the operation, following a hypodermic injection of 4 minims of Magendie's solution. At 4 P.M. she complained of throbbing in the back of the head and vomited.

CASE 20.—The operation was a double orchidectomy for tubercular testicle, at the Brooklyn Hospital, September 25, 1900, in a man, aged 39. Twenty minims of a 2% solution were injected at 1.02 P.M., followed by analgesia to level of third rib in 2 minutes. Pulse just before injection was 100; 26 minutes after injection he received 8 minims of Magendie's solution, after which it was 80. He complained of thirst at this time, and was given a half-ounce of water to drink. He passed a comfortable night, but suffered several attacks of nausea and vomiting the next day. A simple enema was given, which was effectual, after which the nausea and vomiting ceased. There was no headache at any time.

CASE 21.—The operation was the introduction of Harris' segregator, in a man, aged 48, at the Methodist Episcopal Hospital, September 25, 1900. Twenty minims of a 2% solution were injected, followed by analgesia to the sixth rib in 3 minutes, and lasted for more than 1 hour. In 1 hour and 45 minutes the sensation had returned as far down as the knees; 15 minutes later it included the knee; 15 minutes later it had reached the ankle, and 15 minutes later still it was complete. There were no after effects.

CASE 22.—The operation was for the radical cure of inguinal hernia in a female, aged 26, at the New York Polyclinic, September 26, 1900. Examination before operation showed the pulse 78; temperature, 99.4; respiration, 18; sensory symptoms, kneejerk, and ankle-clonus, normal; 20 minims of a 2% solution were injected, and $\frac{1}{4}$ grain sulfate of morphin injected, subcutaneously. Time occupied in making the cocain injection was 45 seconds. There was paresthesia in feet and legs at the end of 4 minutes; analgesia was complete in 9 minutes, and sweating was profuse at the end of 19 minutes; on complaining of thirst, she was given a glass of water. Respirations were sighing, and averaging 24 throughout the operation. The pulse rose to 110 after the analgesia was complete, but fell to 90 at the completion of the operation. Sensations to heat and cold were tested during the operation and found negative. The anesthesia extended as far as the axillae. During the analgesia, the foot-

clonus and kneejerk were tested, and found normal. The sighing respirations ceased at the end of an hour. The patient was sleeping naturally 10 minutes later; 1 hour and 45 minutes following the injection, the sensation had returned; 2 hours and 15 minutes following the puncture, she was again perspiring freely. She complained of headache, and had some nausea and slight vomiting. Two 1-grain doses of caffeine were given at an interval of 4 hours. The headache, however, persisted more or less during the 48 hours following the operation; indeed, it did not entirely disappear until the morning of the third day. The patient was subject to headache, but not so severe as this. Marked thirst was also a decided symptom during the first 3 days. The pulse was slightly accelerated likewise during the first 3 days, and the temperature ranged from 99.4° F. to 100° F. These symptoms were not more pronounced than would ordinarily occur from the operation itself. The urine remained normal in quantity and characteristics. The pupils were not dilated.¹

CASE 23.—The operation was a vaginal hysterectomy in a female, aged 51, at the Methodist Episcopal Hospital, on September 27, 1900. Twenty minims of a 2% solution were injected. Analgesia to the tenth rib was complete in 5 minutes, paresthesia, numbness, and a feeling of formication in the right foot 5 minutes later; 17 minutes following the injection the patient complained of a feeling of heat at the waist, lasting for 25 minutes. At this time she became nauseated and vomited several times during the operation. Forty-two minutes after the injection she complained of burning sensation all over the body, and faintness, calling for water. The pulse was 80 at the commencement of the operation, and 72 at its close, 40 minutes later. Vomiting occurred after the completion of the operation; 2 drams of whisky were given at the end of the operation. Sensation returned in soles of feet at the end of 2 hours. There were no further after-effects.

CASE 24.—The operation was an incision and irrigation for hydrarthrosis of the right knee (Charcot's joint), in a male, aged 59, at the Methodist Episcopal Hospital, on September 29, 1900. The patient was in advanced locomotor ataxia; 20 minims of a 2% solution of cocain muriate were injected. Examination before injection showed almost complete loss of sensation in the left leg. At the end of 7 minutes both legs were completely analgesic, and in 10 minutes the analgesia extended to the border of the ribs, from which point it did not advance. At the commencement of the analgesia the pulse was 90, full, and slightly irregular. During the next 12 minutes it rose to 104, although of good quality. At this time he became somewhat uneasy and slightly nauseated. Within the next 2 minutes there were sighing respirations, and in the next 3 minutes the pulse became markedly irregular and intermittent; 2 minutes later it was as in the beginning, although he was still somewhat anxious and slightly nauseated. He received $\frac{1}{2}$ grain sulfate of morphia 5 minutes following the cocain injection; 1 hour and 20 minutes following the injection the pain sensation had returned at the knee operated upon, but not below; 3 hours and 40 minutes after the injection the analgesia had completely disappeared. Vomiting did not occur at any time. There were no further after-effects.

CASE 25.—The operation was dilation and curettage for fungous endometritis and metrorrhagia, in a female, aged 16, at the Methodist Episcopal Hospital, on September 29, 1900; 20 minims of a 2% solution were injected, and analgesia was complete in 14½ minutes. During the advance of the analgesia there were no abnormal sensations. All parts of the lower extremities were affected at the same time, after which it extended to the free border of the ribs. During the operation it gradually advanced to the level of the fifth rib. There were no abnormal sensations during or following analgesia. There was slight increase of tension and pulse-rate; $\frac{1}{2}$ grain of sulfate of morphia was given 2½ minutes after the cocain injection; 19½ minutes following the injection the patient became slightly nauseated; this passed off in the course of the next 10 minutes. Sensation began to return from above downward at the end of 1 hour, and was completely restored at the end of 2 hours. At this time she again became nauseated and vomited about 2 drams of curdled milk; 2 hours later she again vomited. She com-

plained of headache all night. There were no further after effects.

CASE 26.—The operation was for the radical cure of inguinal hernia in a man, aged 19, at the New York Polyclinic, October 3, 1900. Twenty minims of a 2% solution were injected and 3 minutes after there was analgesia to the knee; in 4 minutes the analgesia had reached to the fourth rib. He now complained of nausea, and 2 minutes later he vomited. The vomiting continued at intervals for 10 minutes, during which time he complained of feeling faint and moaned as if in distress. When the nausea ceased he ceased to moan, and thereafter he only complained when considerable dragging was made upon the wound-edges by the retractors. The peritoneum seemed to resent the contact of my finger after the latter had been rinsed in alcohol, the patient complaining, although in a mild manner, upon such occasions. Involuntary defecation took place at the end of 18 minutes. He complained of thirst and asked for a drink of water. After the nausea ceased, and while the operation was proceeding, he laughed and joked with the members of the class sitting on the front row. The patient was given $\frac{1}{15}$ grain of hydrobromate of hyoscin just before the cocain was administered.

CASE 27.—This was an abdominal hysterectomy for myomatous uterus, in a female aged 38, at the Brooklyn Hospital, October 4, 1900. Twenty minims of 2% solution were injected at 1.06 P.M., followed by analgesia to the third rib in 4 minutes. The patient said the numbness started in her feet and worked up. At 1.12 there was involuntary defecation; at 1.14 she vomited; at 1.20 the pulse was 54; respiration 26. At 1.50 she complained of some pain just below the umbilicus; the pulse was 71. At 1.55 the nausea which had troubled her occasionally disappeared. At 2 she said she "felt the stitches," but did not complain. Caffein citrate, 2 grains, was given hypodermically at this time. At 3 she seemed to be entirely free from the effects of the cocain, and expressed herself as feeling very comfortable. At 4.15 she was seized with a somewhat severe chill, which lasted 20 minutes, and was followed by a headache all over the top of her head. At this time her temperature was 98° and pulse 80. An ounce of whisky was given when the chill appeared, and 2 grains of caffeine citrate for the headache. She passed a comfortable night. There were no further after-effects.

CASE 28.—The operation was at the Methodist Episcopal Hospital, October 4, 1900, on a female, aged 40; an abdominal hysterectomy and appendectomy; 20 minims of a 2% solution were injected at 3.54 P.M. Analgesia to fourth rib was established in 4 minutes; one minute later there was nausea. At 4.07 she was perspiring and complained of feeling faint; there was sighing respiration, the pulse was 60. At 4.09 the sphincter ani was relaxed, with fluid movement. At 4.12 there was a second involuntary movement; respirations were rapid. At 4.20 the pulse was 90 and occasionally omitting a beat. At 4.25 she complained of pain in the epigastrium while appendix was being removed. At 4.40 the pulse was 110; she complained of a slight pain "in the bowels." At 4.50 operation was complete, and the patient left the operating-room smiling.

CASE 29.—The operation was costal resection for gangrene of lung and empyema in a male, aged 36, at the Brooklyn Hospital, October 4, 1900. Before operation the temperature was 102.6 F. and the pulse 120; respirations were 46. The patient was placed on the healthy (left) side and 24 minims of a 1% solution were injected at 3.15 P.M., followed by analgesia to the knees in 5 seconds, and to level of third rib in 3 minutes; 2½ inches of the fifth rib were removed in the axillary line. He complained of pain when the intercostal nerve and periosteum were peeled off from the bone. Analgesia practically subsided in 40 minutes. There was no nausea or vomiting. He had severe headache all night. There were no further after-effects.

CASE 30.—The patient, a male, aged 67, was operated upon for cholecystotomy at the Methodist Episcopal Hospital, October 6, 1900. Twenty minims of a 2% solution of cocain, and 10 minims of sterilized water were injected at 3.31, and the patient placed at once with the hips and pelvis elongated. At 3.36 the analgesia was evident on the level of the tenth rib. At 3.36 he sneezed and complained of nausea; a few seconds later he vomited and at the same time had an involuntary evacuation of the bowels, of which he was conscious. At 3.40 the analgesia was complete to the fourth rib; sighing

¹ For the examination of this patient before the injection, as well as the report upon her condition during the analgesia, and following the operation, I am indebted to Dr. S. Ormond Goldman.

respirations, and parasthesia of the fingers were noted; at 3.41 he was perspiring; he was conscious of pulling sensation at the seat of operation; at 3.43 the pulse was 60 and of good quality; at 3.48 he had a dull sickening sensation at the field of operation; at 3.55 he complained of pain when gauze packing in the abdomen forced the liver against the diaphragm. At 4.10 upon withdrawing the gauze packing from the abdominal cavity the patient complained of dragging pain. At 4.15 the sighing respirations ceased; the pulse was 60, with good quality; at 4.30 there was parasthesia of the feet. At 4.35 the operation was completed and he expressed himself as "feeling fine." At 6.30 he had headache which lasted all night, in spite of caffeine citrate and morphin sulfate. This yielded to phenacetin 5 grains and acetanilid 3 grains every 3 hours during the following forenoon.

CASE 31.—The operation was for ureterocervical fistula in a female, aged 36, at the Brooklyn Hospital, October 9; 20 minims of a 2% solution were injected at 11.40 A.M. and analgesia extending to the supraorbital region was established in 1½ minutes. The pulse before injection was 90, respirations 22; at 10.50 there was sighing respiration for 10 minutes, followed by nausea at 11. At 11.15 the analgesia of the face had subsided, and at 11.25 it had disappeared down to the level of the second rib. The greatest degree of analgesia at this time was near the spine, the least at the middle line in front. She left the operating table at 12.40 with the pulse 120, and respiration 36. Analgesia persisted for 1 hour after returning to the ward. At 2.30 she had a chill lasting for a few moments, followed by severe headache. Whisky given at this time was vomited. At 4 P.M. the temperature was 103.2°, pulse 100, respiration 36. At 8 P.M., temperature was 102.2°, pulse 112, respiration 36. By 8 A.M. of the following day the patient's condition was practically normal.

CASE 32.—The operation was an amputation of a gangrenous toe (the patient a diabetic), in a male, aged 60, at the Brooklyn Hospital, October 9. Twenty minims of a 2% solution were injected at 1 P.M. and analgesia established to the top of the head in 1 minute. The pulse and respiration were unaffected. There were no incidents during the operation. The patient left the operating table at 1.15, and during the afternoon headache gradually came on, for which two 2-grain doses of caffeine citrate were given at intervals of 3 hours. The headache had disappeared by morning. There were no further after-effects.

CASE 33.—The operation was curettage, trachelorrhaphy, perineorrhaphy, in a patient, aged 23, at the Brooklyn Hospital, October 9, 1900. Twenty minims of a 2% solution were injected at 11.51 A.M. and analgesia established in 2 minutes; the extent of analgesia was to level of the fourth rib. At the time of making the injection the pulse was 130 and the respirations 28. At 12.05 there was nausea and vomiting. At 12.30 the analgesia had subsided to the level of the sixth rib. At 12.35 the patient left the operating table with a pulse of 140 and respirations 32. At 4 P.M. the temperature was 99.4° F.; by midnight it had risen to 101.4° F., but fell to 102.4° F. by 4 the next morning, where it remained for 2 days. No vomiting after the first. Headache persisted from the time the temperature rose until the next morning.

CASE 34.—The operation was an excision of veins for varicocele in a man aged 45, at the Methodist Episcopal Hospital, October 9, 1900. Ten minims of a 2% solution of cocain and 20 minims of a 2% solution of antipyrin were injected at 3.35 P.M., and analgesia to level of fourth rib in the axillary line was established in 3 minutes. He complained of pain when the vas deferens itself was being isolated with its accompanying vessels from the veins to be ligated. The operation was completed at 3.50. At 4.30 he was slightly nauseated; sensation was restored above the knee. At 5 the sensation just below the knee was restored, and at 6 the sensation was entirely restored. At 7 he complained of severe headache, and I ordered 1 grain citrate caffeine hypodermically. Later on 5 grains phenacetin every third hour was ordered, and finally ½ gr. morphia sulfate was resorted to. These, however, seemed to have but little effect. The headache ceased upon the evening of the day following the injection. In the meanwhile the patient became very apprehensive and feared he was going to die.

CASE 35.—The operation was a curettage of uterus for fungous endometritis in a female, aged 40, at the Methodist Episcopal Hospital on October 9, 1900. Ten minims of a 2% solution of cocain and a 10% solution of antipyrin were in-

jected at 7.04 P.M. At 7.07 there was analgesia to the tenth rib. Operation was completed at 7.26. During the operation, she was nauseated and vomited frequently. She had not been prepared for in the usual manner. The bowels had not been cleared out by laxatives, and the patient had eaten her usual dinner. Three hours after injection, she suffered severe headache, and the temperature rose to 101° F. Headache, nausea and vomiting continued the next day, in spite of morphin, caffeine citrate, and phenacetin. These gradually subsided, and disappeared on the third day.

CASE 36.—The operation was an abdominal section for extrauterine pregnancy in a female, aged 23, at the Brooklyn Hospital, October 11, 1900. Twenty minims of a 2% solution were injected at 11.42, followed by analgesia to the level of the third rib in 2 minutes. The pulse, before injection, was 114; respirations, 38. At 11.55 the patient vomited, and at 12.25 the skin was cool and moist. The case was one in which rupture had taken place a few days before. A large blood-clot was turned out from the deep pelvis, when copious fresh bleeding took place, and in the effort to hold this in check by pressure until the bleeding vessel could be identified and secured, the patient became very apprehensive and restless, interfering somewhat with the manipulations, although it is believed the patient did not suffer real pain. For this reason chloroform anesthesia was resorted to, the patient passing under its influence without a struggle. Just prior to the administration of the chloroform, the pulse was 96; the respirations continued as at first. At 12.40 the operation was completed. Before leaving the operating table, ⅛ gr. of hyoscin was given subcutaneously. At 2.30 the patient had a severe chill, lasting half an hour. No headache. There was no further vomiting. Two drams of chloroform was used.

CASE 37.—The operation was curettage for endometritis, posterior colporrhaphy, and perineorrhaphy, in a female, aged 39, at the Methodist Episcopal Hospital, October 13. Twenty minims of a 2% solution of cocain were injected at 3.20, and analgesia established in 3 minutes to the level of the clavicle. At 3.25 there was parasthesia and burning sensations all over the body; she was very nervous. The pulse was 150 at the commencement, and continued at this rate throughout the operation, which was completed at 3.35. At 5.30 the sensation had returned. At 8 o'clock the patient vomited; this was repeated several times during the early hours of the night. The patient complained of headache for the better part of 2 days.

CASE 38.—The operation was an inguinal colostomy for carcinoma of the rectum, in a man, aged 68, at the Methodist Episcopal Hospital, October 13. Twenty-five minims of 2% solution of cocain were injected at 3.58. Owing to some difficulty in clearing the inner needle, which had become blocked with a fragment of fibrous tissue, a quantity of cerebrospinal fluid, estimated at 90 minims, escaped. There was analgesia to the level of the fourth rib at 4.08 (10 minutes). Pulse before injection was 98; at 4.15 it was 64; the patient moaned, and had nausea, with some retching. He complained of burning pain when the operator's hands, previously dipped in alcohol, were brought into contact with the peritoneum. Pulse at 4.57 was 78, with sighing respirations; the skin was sensitive to the sharp pointed retractors used. He left the operating table at 5.10 with a pulse of 80, and no further nausea. There was no headache at any time. The patient suffered from retention of urine for 3 days.

CASE 39.—The operation was an excision of hemorrhoids in a female, aged 35, at the Methodist Episcopal Hospital, October 13. Twenty minims of a 2% solution were injected at 5.43 P.M., followed by analgesia to the free border of the ribs in 7 minutes. The patient became talkative and said: "My body feels all in a glow, and the pain I have had for days has all gone." The pulse was as before the injection, 80. The patient left the table at 6.03 with a pulse of 80. At 10.30 the patient was restless and suffered considerable pain in the region operated upon.

CASE 40.—Curettage of uterus was performed at the Brooklyn Hospital, October 18, on a patient, aged 22. Twenty minims of a 2% solution were injected at 11.57, followed by analgesia in the operation field in 1½ minutes. The analgesia finally extended to the supraorbital region. The pulse at the commencement was 138; respiration 42. At the end of the operation the pulse was 136; respiration 26. Analgesia lasted 1 hour and 38 minutes. There was no nausea or

vomiting. There was headache at 4 o'clock the next morning, which lasted for 4 hours, but no other after-effects. The pulse gradually lessened in frequency, resuming the normal in 16 hours.

CASE 41.—Uterine curettage was performed on a patient, aged 35, at the Methodist Episcopal Hospital, October 18. Twenty minims of a 2% solution were injected at 10.50, followed by analgesia to the lower border of the ribs in 5 minutes; it subsequently extended to the arms and head. At 10.59 she became nauseated and vomited, and complained of numb feelings in arms. At 4 P.M. she had headache. At 4.30 she vomited about 4 ounces of fluid, immediately after which the headache vanished. There were no further after-effects.

CASE 42.—Suturing of fractured patella was performed on a male, aged 57, at the German Hospital, October 19; 20 minims of a 2% solution were injected at 12.27. Pulse before injection was 82. Analgesia commenced in the feet at 12.29½, and reached the clavicle at 12.34. Coincident with the latter there was marked cyanosis, when ½ ounce of whisky was given. At 12.35 he complained of thirst. At 12.36 he became nauseated. At 12.37 projectile vomiting took place. At 12.40 he complained of feeling dizzy, and again vomited. At 12.57 the skin was cold and clammy, and an involuntary evacuation of the bowels took place. At 1.05 the operation was finished, with the pulse 104. At 1.12 the cyanosis which had been gradually lessening had entirely subsided. At 1.20 the analgesia had subsided to the second rib; at 1.36 it had subsided to the fourth rib; at 2.06 sensation had entirely returned. At 4 P.M. the temperature was 103.8° F., and the pulse 118. At 4.30 he complained of intense, "bursting" headache, became delirious, and had to be strapped in bed. At 5.30 the temperature was the same, but the pulse was 148, and the respirations 24. An hour later, following a sponge-bath, the temperature had fallen to 104° F., and the delirium became of a milder type. The temperature fell at midnight to 100.6°, the pulse 112. The more threatening symptoms gradually subsided, although the headache, dizziness, and some vomiting persisted for 54 hours following the injection. The last urine (10 ounces) passed prior to the operation, was at 4 A.M., which, upon examination, was found to be of a specific gravity of 1.020, of acid reaction, with no albumin, sugar, or casts; triple phosphates were found. The first urine obtained after the operation was by catheter at 4 A.M., of the following day (16 hours after the injection), and was only 2 ounces. An examination of this urine showed a specific gravity of 1.030; no albumin or sugar; hyalin casts (a few). At 12 noon, involuntary urination took place, and apparently a normal quantity. At 7 P.M., 16 ounces passed, from which time the average daily amount was normal.

Comment.—A few words in passing upon some of the prominent features of the case may be in order. It is the only case in which symptoms occurred to give me real anxiety. There certainly was present most profound disturbance of the different centers, as shown by the cyanosis, projectile vomiting and persistent vertigo. That the inhibitory heat center was likewise affected is shown by the sudden and extreme rise of temperature, and the fact that abstraction of caloric from the body by simple sponge baths quickly brought the temperature down and held it until the effect of the disturbance upon the center itself had passed off. How much the delirium and persistent vertigo depended upon the renal condition, and the latter, in its turn, depended upon the injection, is difficult to estimate under the circumstances. In view of the fact, however, that practically no urine was secreted during the 8½ hours prior to the injection (which fact was not known to me at the time of the operation, owing to the failure to report the circumstance), and that only 2 ounces were obtained at the end of 16 hours after the injection, it is fair to assume that whatever the conditions which gave rise to the suppression, these were in existence before the injection. It is interesting to contrast the post-operation urinary history of this case with that of Case 44, in which a single kidney, after a nephrectomy,

in which some comparative, if not temporarily complete suppression is to be expected, secreted 21 ounces during the first 24 hours following operation, 8 ounces of which were obtained during the first 7 hours.

CASE 43.—The operation was an introduction of Harris' segregator in a male, aged 29, at the Methodist Episcopal Hospital, October 20. Twenty minims of a 2% solution of cocaine were injected at 3.45 P.M., followed by analgesia to the level of umbilicus in 4 minutes. There was no nausea or vomiting while in the operating room. At 4.50 P.M. he was nauseated. At 5 P.M. sensation returned down to the knee. At 5.20 sensation existed half way between the knees and ankles. At 5.30 to the ankles. At 5.40 he had cramping pains from the knees down, lasting about 5 minutes. At 6 P.M. sensation was entirely restored; at 9.45 he complained of severe headache, which persisted until 6 A.M. the next day. There were no further after-effects.

CASE 44.—Nephrectomy for old pyelonephritis was performed on a female, aged 47, at the Methodist Episcopal Hospital, October 20. Twenty-five minims of a 2% solution of cocaine were injected at 5.15 P.M. with the patient in the semiprone, or Sims' position. At 5.51 analgesia extended to the thigh, and at 5.57 to the fourth rib. At 6.20 there was hot sensation all over the body, but no discomfort. At 6.35 she left the operating table with pulse and respiration unaffected by the injection or the operation. There was no nausea, vomiting, or headache. The urinary record for the first 24 hours shows 21 ounces. There were no after-effects.

The following case is presented as a contribution to this subject, although it was not a case of spinal cocaineization:

A patient, aged 25, was operated upon by curettage for endometritis, at the Brooklyn Hospital, October 18, 1900. Thirty minims of a 2% solution of antipyrin were injected at 11.57. Analgesia was apparently established in 5 minutes to the level of the nipples. Pulse before injection was 112; respirations 34. At 12.45 the pulse was 130, and respirations 36. At 12.50 the pulse was 120 and respirations 26. There was no nausea or vomiting while in the operating room. Upon returning to the ward the patient slept for a while. At 4 P.M. she complained of severe pain in the temporal regions. At midnight she had nausea and vomiting, which lasted more or less all night. The headache persisted and was severe for 26 hours following the operation. The temperature began to rise 8 hours after the operation, reaching its maximum, 101° F., at midnight, 12 hours after the injection. No medication was employed in this case.

In looking over the notes of this case of antipyrin injection one is struck with the resemblance it bears in many of its features to those in which cocaineization was employed. There can be no doubt that some degree of analgesia was established in this case, although to what extent it was difficult to determine, owing to the fact that the patient was a stoical Italian woman, of a low order of intelligence, and who did not understand English. She did not shrink when pricked with a needle, or during the operation, but it was observed that her facial expression at times during the operation was such as to suggest that she was not entirely indifferent to what was going on. The most interesting points in connection with the case, however, relate to the occurrence of the nausea, vomiting, headache, acceleration of pulse, and rise of temperature, these being quite up to the average of those observed in connection with spinal cocaineization.

The Technic.—As a result of experience gained in this group of cases I would insist that the following points be borne in mind:

1. The entire lumbar and sacral region including the site of the *cristi illii* upon either side should be carefully prepared as if for an extensive operation upon these parts. This for the reason that in locating the point for making the

injection, more or less contact of the surrounding parts with the surgeon's aseptically prepared hands is inevitable.

2. The point of selection for making the puncture is in the third lumbar interspace, *i. e.*, between the third and fourth lumbar vertebrae. The position of the patient may be upright or in the semi-prone position of Sims. My own plan is to have him sit crosswise upon the operating table, with his lower limbs hanging loosely over the table. With the patient's trunk well erect the surgeon's middle finger of each hand is placed upon the highest point of the crest of the ilium of either side, while the thumbs are approximated upon the same level in the middle line. They should meet at the fourth lumbar spine. The patient now bends forward in the position of ventral flexion, with his elbows resting upon his knees, when a perceptible widening of the space between the third and fourth spinous processes is apparent. The thumb of the left hand remains in position to identify the interspace, while with the right hand the surgeon injects a small amount of the cocain solution about one centimeter to the right of the interspace. With the point of a scalpel a slight puncture is now made on a line midway between the spinous processes and in the area of skin anesthetized. This puncture is very superficial, and serves to permit the passage of the puncturing needle into the depths without danger of infection from microorganisms in the skin itself, as well as to prevent the lumen of the needle from being occluded from a punched-out plug of skin, as happened in one of my cases. The needle employed should be between one and two millimeters in circumference, not larger, with a moderately short or blunt bevel, and about 3 cm. long. The syringe used for making the injection should be capable of sterilization by boiling, such as the glass syringe with asbestos packing.

The needle should be pushed steadily forward and slightly toward the left, so as to enter the canal at a point in the median line. This entire procedure is painless, as a rule, from the time the first needle puncture is made in making the preliminary subcutaneous injection. The entrance of the needle into the spinal canal is announced by the escape of the clear spinal fluid. When this is assured the injection is made.

The amount of cocain used is from $\frac{1}{16}$ to $\frac{1}{8}$ of a grain dissolved in sterilized water and again sterilized after solution is effected. From 15 to 20 minims of a 2% solution is quite sufficient under most circumstances for the average adult. About a minute is taken to make the injection in order to permit the latter to mingle thoroughly with the spinal fluid before withdrawal of the needle, since probably more or less escape occurs through the puncture-opening in the meninges, in which event there is some loss. A little collodion is pencilled about the skin puncture as the needle is withdrawn. The patient is at once placed in the recumbent position and preparations for the operation proceeded with.

Errors and Accidents in Making the Puncture.—A vessel may be punctured by the needle, and a clot form, obstructing its lumen, so that, upon reaching the spinal canal, no fluid will flow. This will be suspected, if the needle travels forward for quite a distance with decided lessening of the resistance felt at first, and finally impinges against the anterior bony wall of the spinal canal. To lessen the liability of puncture of a vessel, the needle-point should have a rather short bevel. A further precaution is to have an exhaust-bulb attached to the needle after it has penetrated a short distance. Blood entering the needle will then be aspirated at once from the latter before a coagulum forms. Under no circumstances must the injection be made until the clear fluid is obtained, and that in sufficient quantities to place beyond the possibility of a doubt the fact that the canal has been entered. In two of the failures occurring in my hands a rather thick fluid was obtained. I have not yet determined where this fluid came from. If from the subarachnoid space, it was not normal cerebrospinal fluid.

If the surgeon feels assured that the needle has entered the canal, and still the characteristic limpid fluid is not obtained, he should resort to aspirating the needle with the syringe attached, rather than withdraw the needle and make a fresh puncture. It is very undesirable to make more than one puncture, since this increases the chances of loss of the cerebrospinal fluid, the presence of which is necessary to a diffusion of the cocain, and, of course, of the cocain-solution itself, when this is finally successfully placed in the canal.

The needle may impinge against the bony structures on its way to the canal. Should this occur, the instrument should

be partially withdrawn, and its direction changed so as to conform with the proper route to be taken in order to reach the canal. To attempt to change its direction without withdrawing it sufficiently far to clear the bone, will risk breaking the needle, in case a steel needle is used. The accident of breaking the needle may also occur from a sudden movement on the part of the patient, the chances of this happening being increased by the fact that a fine steel needle is employed. To use a larger needle, however, is undesirable. To the circumstance of using a large needle and the consequent leakage of a portion of the cocain solution mingled with the cerebrospinal fluid through a large puncture, is to be attributed, at least, one of my complete failures; and the fact that in another case the analgesic effect was not sufficiently prolonged to complete a posterior colporrhaphy after an anterior colporrhaphy had been performed.

Since the accidents thus far mentioned are of a character to be overcome by proper instruments and careful technic they should not deter surgeons from trial of the method. I have endeavored to overcome the mechanical difficulties by an apparatus of simple construction, and which, in the trials I have given to it, seems to work satisfactorily. The needle portion is double, that is to say, one needle passes inside of another, the inner or finer needle passing about a centimeter beyond the outer when projected. The needles are made of 14 karat gold, or platinum with 3% of iridium as an alloy, are sufficiently hard to hold a point well, and tough and flexible enough to withstand any ordinary strain. The inner needle is locked in position by the common bayonet-joint device, is capable of being withdrawn for the purpose of clearing from blood-clot, if necessary, and may be reintroduced along the same track to and into the original opening in the spinal meninges, the outer needle serving as a guide for this purpose. In this manner more than one puncture in the meninges is avoided. A simple aspirating device may be attached to the needle in order to prevent occlusion by blood-clot, and at the same time this will serve to give early warning of the entrance of the needle into the canal by the prompt flow of the fluid which in some subjects occurs but slowly without aspiration. This device also places under the surgeon's control the amount of fluid withdrawn. The instrument which I have evolved from my own experiences consists of a double needle with a bayonet-joint lock, a piece of rubber tubing in the course of which a small glass bulb to catch the fluid is placed, and a stop cock to hold the vacuum secured by the attached bulb.

The instrument is introduced with the needle-points level, the bulb compressed, and the stop-cock turned so as to hold the vacuum in the bulb. Just before the proper depth, as previously estimated, is reached, or when the needle has penetrated about 4 cm., the inner needle is projected and the stop cock turned so as to permit the vacuum to act upon the lumen of the needle. If the needle remains clear and the proper direction has been taken the fluid from the canal is seen to flow into the little glass bulb as the instrument is advanced. If all the conditions have been apparently fulfilled and the flow does not occur, the inner needle is withdrawn, cleared and reintroduced through the outer needle, which has been left in situ, a new vacuum having been obtained, which is turned on when the inner needle has been introduced its entire length. The aspiration apparatus is now detached, the syringe attached, and 20 minims of a freshly prepared 2% solution slowly injected.

In the absence of the cerebrospinal typical fluid, and before I had learned to avoid errors in the technic I was compelled to abandon the method in the individual case and proceed with the operation under ether or chloroform anesthesia. This was also done in the cases in which the analgesic effect was not sufficiently prolonged to permit of the completion of the operation. No disturbances in the usually-observed phenomena of general anesthesia resulted from the preliminary use of the subarachnoid cocainization, save that rather less of the anesthetic agent was required than usual.

In the cases in which the method was completely successful there was usually ample time to complete the

* Rather than submit to the annoyance of waiting for the needle to be cleared it is better to have a second or duplicate inner needle at hand.

average or even the sometimes necessarily long operations, or those lasting for more than an hour.

The question of the effect of cocain injections upon the cord itself is one of great interest. Nicoletti, of Naples, has shown by experiments upon rabbits and dogs that there are no histopathologic lesions of the nervous system following subarachnoid injections of this drug. Dr. Wm. Browning, neurologist to the German and Brooklyn Hospitals, made careful examination of 11 of the cases in this group at periods of time varying from an hour to a week following the analgesia. The results were negative, and as far as these examinations go, as well as Nicoletti's experiments, no interference with the cord itself is to be feared. I did not hesitate, therefore, upon the basis of Nicoletti's experiments and Dr. Browning's findings in my own cases, to employ the method in a case of advanced locomotor ataxia.

The method cannot, as far as my experience goes, be applied to abdominal section cases involving acute inflammatory intraperitoneal lesion of the abdomen and pelvis. This is unfortunate, since it is in the more despatch-rate of these that the surgeon frequently desires to avoid ether and chloroform. In the single case of appendicitis in which I made use of this method the patient complained very decidedly whenever the inflamed peritoneum was manipulated.

Experiments have been made, notably by Nicoletti, of Naples, to produce analgesic effects in animals by the subarachnoid injection of drugs other than cocain, such as ergotin, antipyrin, and quinin. These have been successful, so far as the abolition of pain may be judged in the lower animals. The effects of drugs applied in this manner upon the human subject has not yet been determined, with the exception of the case of antipyrin subarachnoid injection herewith reported; and in this I believe that the solution was too weak to completely accomplish the object. I am of the opinion, however, that the effects supposed to depend upon the toxicity of the drug are not so much due to this cause as to the disturbance of the cerebrospinal centers by the introduction of a fluid foreign to the environment. That these are not due to the withdrawal of the cerebrospinal fluid is at least suggested by the fact that this fluid escaped in much larger quantities in some of the cases which suffered the least from severe symptoms, and that the latter occurred in most pronounced manner in cases in which the least amount of cerebrospinal fluid was lost.

As to the manner in which the cocain solution affects the nerve structure, the observations of Lewandowsky³ are of interest. This observer asserts that the cerebrospinal fluid partakes of the nature of lymph, is a specific product of the brain, and represents that part of the lymph originating through organic action. Experimentally it was shown that strychnin and ferrocyanate of sodium, when introduced into the subdural space, passed directly into the nerve-substance through its lymph-channels and without the intervention of the circulation. If these experiments are confirmed, it is reasonable to suppose that the cocain gains entrance into the nerve-substance in the same manner. This mode of entrance will likewise explain the extreme rapidity with which analgesia is effected—as, for instance, in one of my cases, in which analgesia up to the ankles was obtained in 5 seconds.⁴

The following is a list of the operations in this series for which the method was used.

	OPERATIONS.
Excision of hemorrhoids.....	5
Abdominal section for appendicitis.....	1
Tenosynovitis of inner hamstring.....	1
Ligature of both internal saphenous veins..	1
Vaginal hysterectomy.....	2
Colporrhaphy and perineorrhaphy.....	2
Curettage, trachelorrhaphy & perineorrhaphy	2
Radical cure of hernia.....	4
Curettage and trachelorrhaphy.....	2
Excision of suppurating vulvovaginal gland..	1
Abdominal hysterectomy.....	2
Double orchidectomy.....	1
Introduction of Harris' segregator.....	2
Arthrotomy of knee.....	1
Uterine curettage.....	3
Abdominal hysterectomy and appendectomy	1
Resection of rib.....	1
Cholecystotomy.....	1
Urethrovessical fistula.....	1
Amputation of toe for gangrene (diabetic)....	1
Excision of varicocele.....	1
Abdominal section for ectopic gestation.....	1
Curettage, posterior colporrhaphy and perineorrhaphy.....	1
Inguinal colostomy.....	1
Suture of fractured patella.....	1
Nephrectomy.....	1
Total.....	41

In 41 cases in which the method was successfully carried out analgesia was established as follows:

	CASES.
Between 1 and 2 minutes in.....	4
" 2 " 3 ".....	5
" 3 " 4 ".....	10
" 4 " 5 ".....	5
" 5 " 6 ".....	4

⁴ But one case in this series proved fatal, and that one of the abdominal hysterectomies from intestinal parasites on the sixth day.

INTRASPINAL COCAINIZATION FOR SURGICAL
ANESTHESIA.¹By S. ORMOND GOLDAN, M.D.,
of New York City.

WHILE intraspinal cocainization as a method of producing general local anesthesia may displace nitrous oxid, ether, and chloroform for operations in the abdomen, pelvis, lower extremities, and to some extent the chest, I do not doubt it will, if nothing more, find a place in selected cases where for any reason it is found undesirable to administer a general anesthetic. That it will be used to the exclusion of other anesthetics I do not believe; for from a considerable experience in the administration of these agents I find that superior results do not lie in the use of any single anesthetic and method to the exclusion of others, but in their proper selection to the case in hand. This the operator has come to place largely in the hands of the skilled anesthetist, realizing the best interests of the patient are subserved by permitting him to use his own discretion.

Medullary narcosis is being subjected to a rigid criticism—if of questionable efficacy the sooner decided the better; if of value in spite of all objections (and so far they have been largely theoretic) it will take its place as one of the methods of anesthetization.

It was a somewhat unique experience to see the uterus and appendages removed by celiotomy—the patient being perfectly conscious, completely relaxed, and anesthetic—this impressed me so forcibly that as an anesthetist the subject had for me more than an ordinary interest.

That to Dr. J. Leonard Corning, of New York, belongs the credit of first producing anesthesia by the injection of cocain into the spinal cord in 1885 I think none will deny; in an interesting series of papers he describes experiments upon the spinal cord of animals followed by the use of cocain injected in the human subject for certain painful affections of the cord which up to that time had not, from the methods then in vogue, given very satisfactory results. At first at a loss how to bring his medicament as close to the cord as possible without injuring it, he devised a technic derived from definite measurements of the spinal vertebrae by which he could deposit his solution close to the membranes;—and with the most satisfactory results, differing in no essential from the results obtained by more recent investigators.

Dr. Corning supposed that the cocain was carried to the cord by means of the veins to a certain extent localized by the sluggish circulation known to exist at the lower part of the cord. He did not use the very practical method of first obtaining the subarachnoid fluid. What he probably did was to deposit his solution partly into the subdural space, which while anatomically separate is in all probability one with the subarachnoid. That his solution only partly entered the subarachnoid space is proved by the absence of toxic symptoms, as he injected in most of his cases $1\frac{1}{2}$ grains of cocain. Quincke in 1890 devised the present lumbar puncture for the removal of cerebrospinal fluid in cases of hydrocephalus; while he injected other fluids into the subarachnoid space he did not inject cocain. Bier in 1898, finding cocain unsatisfactory in the more major operations, thought it possible by the

lumbar puncture to produce anesthesia throughout greater areas; a patient presenting, he used the subarachnoid puncture and injection with entirely satisfactory results; the operation consisting of resection of a tubercular capsule and bones of the foot; this may be said to be the first operation performed with intraspinal cocainization. Bier at this time reports altogether six cases, all satisfactory, then gives an interesting account of the lumbar puncture upon himself; as the syringe did not fit the needle and having lost considerable cerebrospinal fluid it was decided to defer the injection. The spinal puncture and injection of cocain was then made upon Dr. Hildebrand; his well-recorded physiologic symptoms were much the same as those developed in patients at the present time. The very complete and interesting papers describing the technic, with report of cases of intraspinal cocainization which attracted universal attention, were due largely to the efforts of Tuffier, to be followed later by Kreis and other numerous investigators both in Europe and America.

As the most serious theoretic objection to the method I have up to the present time heard is possible injury to the spinal cord itself, the consideration of a few anatomic facts will not be without interest. The spinal cord by means of its surrounding membranes forming its ligaments is contained in a bony cavity considerably larger than the cord itself. It extends from the lower part of the bulb above at the upper border of the atlas to the lower border of the first lumbar vertebra, where it ends in the conus medullaris, descending a short distance as gray matter into the filum terminale of the pia, which descends in the center of the cauda equina to the upper part of the sacrum. The cord is capable of movement from one half to one inch. Three membranes surround it and are prolonged for some short distance on to the nerve-trunks as they emerge from the cord. The pia, the highly vascular and closely adherent membrane, surrounds the cord and is separated from the central delicate membrane, the arachnoid, by a considerable space containing a clear fluid, the subarachnoid space and fluid. Numerous trabeculae covered with endothelium unite the pia and arachnoid. Between the parietal layer of the arachnoid and the external membrane, the dura, is another space, the subdural, containing a slight amount of fluid only. The two outer membranes extend considerably lower than the cord itself, that is to the second vertebral section of the sacral bone. We have simply to remember that the cord is entirely surrounded by a water jacket; the subarachnoid fluid and outer membranes extending considerably lower than the cord itself, forming as it were a culdesac.

I believe the determination of value of any new method depends largely upon the completeness of the observations recorded. For this reason I would propose the use of some such blank as the following:²

The technic of intraspinal cocainization is essentially Bier's and is carried out by means of a sterilized 2% solution of cocain, syringe, and long needles. It may be said there is no operation in surgery in which more rigid asepsis is necessary. The method being so simple I prefer making the solution myself and always fresh before using, at the same time seeing that all instruments, etc., are properly sterilized. The armamentarium I use consists of a 120 m. graduate small shallow glass for the cocain solution, test-tubes, spirit lamp, glass flask with sterilized water, syringe, and needles, test-tubes containing sterilized cotton, a variable number of papers, each containing $1\frac{1}{2}$ grain hydrochlorate of cocain. These papers are then covered with foil and are carried in a wide mouth glass-stoppered bottle. All these things being carried in a small copper sterilizer, 8 x 6 x 2. All the glass materials are sterilized in plain water 12 minutes. The syringe, either glass or metal, is of the solid piston variety, and is entirely separated, which with the needles and stylets are likewise boiled. It is suggested that the needles and syringe should always be kept separate and never used for any other purpose.

As upon the needles I believe often depends the success or failure of the method, it is important to say a few words regarding them—they should according to Tuffier consist of from 7 to 10 cm. in length, having an external diameter 1.1 mm., internal diameter .8 mm. In general terms it may be said that the finest needle

should have a short bevel and as sharp an edge as possible. While steel needles will answer they have the disadvantage of rusting inside and out. To prevent this, after use they should be passed through the flame to heat and so dry the interior. The external part of the needle may be gold or silver plated, being smooth they pass through the skin and avoid rusting which always follows repeated boiling.

The platino-iridium needles answer satisfactorily. They do not rust, but being softer than steel they bend though they do not break. They are, however, too soft to be used repeatedly with satisfaction. It occurred to me I might find in gold a needle occupying a place between steel and platinum. This I have succeeded in doing, having them made with an entirely original feature based upon the anatomic arrangement of the spinal canal. From the examination of several series of lumbar vertebrae I find the distance from the mid-point of the lamina obliquely across the spinal canal to the point where the transverse process joins the body averages 2 cm. It occurred to me that the

FIG. 3.—A. Author's bevel; B. Tuffier's.

essential part of a needle would be in no case greater than this distance, but actually only half or 1 cm., which probably never exceeds the distance from the bony lamina to the subarachnoid space. If the spinal puncture were made with the tissues separated down to the bony lamina an ordinary hypodermic needle would answer, but as the puncture is made with the tissues in place we must allow for the distance from the surface of the skin to the edge of the lamina of the spinal canal. Upon these points I had after considerable difficulty made what I term attenuated needles, which from every standpoint leave nothing to be desired. These may be of two lengths, 6 and 8 cm.; from the point which has a short bevel,—I allow 3 cm. for attenuation. This permits of repeated sharpening and beveling of the tip without diminishing the part of

the needle which enters the spinal canal. The needles of one piece are made of 14-karat gold, which not only avoids rusting but permits the tip being sharpened by oneself by using a piece of jeweler's oil stone. The stylet made of gold is also attenuated—by this means any foreign material may be removed. The measurements of the needles are: Attenuation, external diameter, .8 mm.; internal diameter, .4 mm. Large part, external diameter, .9 mm.; internal diameter, .8 mm.

The cocain solution is always freshly made by myself as follows: A sterile test-tube is partly filled with water from the flask and boiled five minutes—the excess over quantity required is poured off, in this case all over a dram; the powder of cocain is then introduced and the solution maintained just below the

FIG. 1.

FIG. 2.

through which the cerebrospinal fluid will slowly drop is the best to employ; the ordinary large-calibered aspirating needle is, I have found, too large, and no doubt often the cause of failure in these cases in which anesthesia is not produced, though there is no difficulty experienced in obtaining the spinal fluid. The needles

boiling point for one minute. This insures a sterile solution without any deterioration of the cocain. The solution should never be kept from day to day.

The patient should be placed preferably in the sitting position though the side posture may be used when necessary. The back should be prepared as for operations from the lower dorsal region above to the upper part of sacrum below and laterally as far as the iliac crests; the hands being thoroughly prepared, the iliac crests are determined, and an imaginary line taken uniting them. This line at the mid-point of the back passes through the spinous process of the fourth lumbar vertebra; a point below, that is, between the fourth and fifth vertebrae, about 1 cm. external to the spinous process is selected as the site of puncture. The patient is instructed to bend forward, which separates the vertebra to a slight extent when the unattached needle without the stylet is quickly introduced through the skin—the patient may be prepared for the slight temporary pain of the needle, or if desired the site of puncture may be first anesthetized with cocain. The

FIG. 4.

needle is then very slowly pushed in a direction from without inward, and passes without difficulty through the tissues of the back, between the arches of the contiguous vertebra and the outer membranes of the cord into the subarachnoid space. As soon as the needle is in the subarachnoid space, and not until then, the cerebrospinal fluid will flow, usually drop by drop. This may, if desired, be permitted to enter a sterile test-tube; from 5 to 10 drops may be permitted to flow, when the syringe previously filled with the required quantity of the cocain solution is adjusted and the solution slowly injected, consuming from thirty seconds to one minute. The needle should not be removed for two minutes after the injection. It may be said that no case is a success nor should cocain be injected where the cerebrospinal fluid has not been obtained. The needle is then quickly withdrawn, the site of puncture covered with collodion and gauze, and strapped; the patient may then be prepared for operation.

In time varying from 4 to 20 minutes, if the puncture has been successful, the patient will be anesthetic and

ready for operation. The first symptom indicative of successful injection will be a paresthesia of the lower extremities indicated by remarks from the patient such as a feeling of pins and needles, or being asleep or dead as they express it. A short history of each case with remarks will perhaps indicate the symptoms one is apt to encounter better than a general statement.

CASE 1.—The puncture was between the fourth and fifth vertebrae. Spinal fluid dropped freely. Cocain solution was injected, 15 m. of 2% solution. Absolutely no result so far as anesthesia was concerned. After seeing no fault in the technic I could only attribute failure to the cocain. I then learned the solution had been made fresh the day before. Having decided to use a second injection I prepared the solution myself. The puncture was again made—this time upon the left side when the spinal fluid easily flowed; 20 m. of a 2% solution of cocain were again injected, which likewise resulted in failure; the operation, dilation, and curettage, was performed without an anesthetic. The patient's pulse rose to 120; respiration, 24; temperature, 99.2°. The pupils were somewhat dilated; room dusky. Being unable to account for the failure I took both solutions of cocain and tested them physiologically upon myself, in the eye and mouth, as did also the operator. The anesthetic properties of both solutions were not in the least altered. At this time the explanation of the absence of results was inexplicable.

The explanation of failure I believe to be the large-sized needle employed, for the membranes of the cord are tense, and after perforation with a large needle the fluid may pass out between the membranes and bony wall of the canal, exerting no anesthetic or deleterious influence.

CASE 2.—In the second patient the cocain solution was prepared by myself. Only one puncture was made, the surgeon not wishing to subject the patient to unnecessary delay. Fluid dropped freely. Anesthesia was a complete failure. In this patient 20 m. of 2% solution was used. I might say in this case as well as the first, the precaution was taken to see whether the fluid was lost at the end where the needle was adjusted to the syringe. Absolutely none appeared and to all indications it was injected into the subarachnoid space. The patient had no subjective symptom attributable to the injection excepting slight dilation of pupils. Chloroform was administered throughout the operation. I might say this cocain solution was tested upon myself, and also produced local anesthesia when injected beneath the skin, and also applied to the mouth.

Seeking for an explanation of the absence of effects in these cases, which to me were inexplicable at this time, I had recourse to Tussier's article and found the needle he used was very much smaller than mine. I then provided myself with a smaller needle to be used in Case 3.

CASE 3.—This was a case of pelvic abscess. After spinal puncture the fluid flowed freely. I injected 20 m. 2% cocain solution. The patient 5 minutes after injection complained of a dead feeling in the feet which quickly extended to the waist line; sensation slightly abolished. Operation was extremely painful, but no anesthetic was employed. After the patient was returned to bed I remained one hour. She was completely analgesic from the middle of thighs down; as she expressed it, you might take her foot or leg off and she would not feel it, though paresthesia extended to her waist. There was no nausea or vomiting. The respirations were 26; pulse, 110; the pupils slightly dilated, reacted to light and accommodation. There was profuse perspiration; patellar reflex and ankle-clonus were present.

CASE 4.—S. H., aged 22, was a male, anemic, very thin, and emaciated. His pulse was 118; temperature 99.6; had had several operations for dilation of sphincter and stricture of the rectum. The patient, according to the surgeon, could never permit examination without an anesthetic.

Lumbar puncture was performed at 4 40 P.M., between the

fourth and fifth vertebrae. Fluid was obtained in a test-tube; 20 m. 2% cocain solution was injected. Feeling of weight in feet was noted, and heat, also like pins and needles, in left foot particularly. Slight headache was complained of at 4.50. Pupils were normal, sensation to heat and cold absent. Anesthesia existed up to the iliac crest. Stricture was dilated and all manipulations were without pain. Patient, when taken to ward, 25 minutes after operation, vomited exceedingly. In bed afterward, his pupils were normal. Profuse perspiration existed, but no headache; anesthesia was still present at 5.15. He left the hospital next morning. No elevation of temperature existed at any time; sensation was fully restored at 7.20. The following morning he had severe headache; when he left hospital he was given $\frac{1}{10}$ grain nitroglycerin.

CASE 5.—F. F. was somewhat anemic and thin. Spinal puncture was carried out between the fourth and fifth lumbar vertebrae, and the fluid dropped slowly. I injected 20 m. 2% cocain solution, prepared as in Case 3. Time consumed in injection was 35 seconds. At 10.46 there was a tingling sensation, though pain was diminished. Abdominal oophorectomy was performed by incision at 10.50. There was no pain during the entire operation. At 10.55 pulse was 100, respiration 28; at 11.15 pulse 100, respiration 26; at 11.25 the pulse was 110, respiration 26, temperature 98. Profuse sweating, but no nausea, vomiting or headache occurred at any time. This patient subsequently developed bronchitis and localized pleurisy, and had a rapid pulse and respiration, and high temperature. The first day after operation the temperature varied between 100.4 and 101; pulse 88 to 104; respiration 24 to 28. There was pain in the side, but no headache; there was cough; the urine was negative—the amount 27 ounces. On the second day the pulse-rate was 84 to 104; temperature 100 to 100.2; respiration 24 to 36. Urine 23 ounces. There was no headache. On the third day the temperature was 100.2 to 101.4; respiration 24 to 36; pulse 94 to 102. There was pain in the chest. Anesthesia was a complete success in this patient, extending to the axillae. The case is also interesting to those who always attribute bronchial and pulmonary complications after operations to the anesthetic. I have not been able yet to connect the spinal puncture with the patient's chest. The temperature, pulse, etc., gradually approached the normal after the sixth day.

CASE 6.—L. M., aged 30, was of a plethoric type. Temperature was 98, pulse 80, respiration 18. He had varicose veins. Lumbar puncture was made between the fourth and fifth vertebrae at 3.20, fluid dropped slowly, and I injected 20 m. 2% cocain solution. Dead feeling in the feet followed almost immediately; when the patient lay down, sensation to a pinprick was felt as a dull, not sharp pain. At 3.26 anesthesia was absolute to the axillae. At 3.28 nausea and vomiting occurred, lasting to 3.30, then ceased entirely. Respirations were 28, pulse 110; he was sweating considerably. Operation began at 3.30 and finished at 4.00 P.M., the patient still completely anesthetic. There was no difficulty in breathing, and no headache; the pulse was full, the pupils normal. Sensation, at 4.35, began to return in the right leg first—was complete at 5.00 P.M. He had considerable frontal headache that night which phenacetin and caffeine seemed to relieve, though he had a dull feeling about the head all the next day. He has had no headache since.

	3.30 P.M.	3.45 P.M.	4.00 P.M.	4.30 P.M.	5.00 P.M.
Pupil	Normal.	Normal.	Normal.	Normal.	
Pulse.....	110	120	120	110	110
Respiration,	28	28	26	26	26

The day following, the temperature was 100, after which it returned to normal; pulse 78; respiration 20; the pupil normal. Reflexes were not involved during anesthesia.

CASE 7.—Mrs. L. weighed 130, and was anemic, the pulse 70; respiration 20. The woman was in labor, with a normal presentation. Puncture was made at 3.50 A.M., between the fourth and fifth lumbar vertebrae; at 3.54 there was paresthesia, the toes and feet being cold; the buttocks were numb, painless to examination, and a feeling of warmth existed up and down the legs. She wished to go to bed, but felt she could not because of the dead feeling in lower extremities. She did so, however, with help; there was no sensation to pain, the pulse was 128; respiration 28. She vomited at 4.20 and retched considerably. Fetal heart-sounds were normal, and

the uterine contractions, I was told, were undiminished; perspiration was profuse, the mouth dry; she had muscular tremors; at 4.25 respiration was increased in rapidity to 60, short and gasping, the pulse 140. The patient was blanched, profusely perspiring, and restless. She had every symptom of shock for about ten minutes; she gradually improved, felt better and the pains returned. A second injection, was not made, but a whiff of chloroform was given when the head was about to be born. In 20 minutes the placenta was expressed. The operator told me shortly afterward the patient went into collapse with no pulse and a blanched color; she was inverted, and hot saline enema was given, when she gradually improved. I saw her shortly afterward when her pulse was 106 and respiration 26. I subsequently was told she had very severe headache for two days following confinement, for which nitroglycerin, caffeine, phenacetin, etc., were given without lessening its severity to any extent. This case was noteworthy for the short anesthesia, 40 minutes, and great amount of systemic effect from the cocain.

CASE 8.—M. H., aged 32, was somewhat anemic, pulse 78, respiration 18, temperature 98°. Operation was for dilation and curettage and repair of the cervix. An ounce of whisky was given. Lumbar puncture was effected at 5.01 P.M., between the fourth and fifth vertebrae, followed by the injection of 20 m. of 2% cocain solution; at 5.03 the left leg was dead first; at 5.05 both legs to the hips, then to the axillae, were anesthetic while movement was unimpaired; the knee-jerk and ankle-clonus were present; the patient vomited at 5.10. Operation began at 5.15 and ended at 6.00, the patient still anesthetic, and having felt absolutely nothing. Sensation to touch was preserved; he felt good throughout.

	5.10 P.M.	5.20 P.M.	5.30 P.M.	5.45 P.M.	6.00 P.M.	6.30 P.M.
Pulse	100	110	110 small	60	100	100
Respiration 24		28	28	28	24	24

At 6.10 sensation commenced to return and was complete by 6.30. There was slight headache the day following, which stopped without drugs. On the following day temperature was 99.4°, the pulse 86, the respiration 18.

CASE 9.—Mrs. G., aged 34, stout, was operated upon for colpoperineorrhaphy and ventral suspension. Puncture was done at 9 A.M. between the fourth and fifth lumbar vertebrae. The fluid dropped slowly; I injected during 40 seconds 20 m. 2% solution of cocain. Within ten minutes the operation was begun. The patient was sensitive; no analgesia was present though vaginal operations were finished; chloroform was given for abdominal operation. After opening the abdomen chloroform was discontinued, to see if the patient felt anything. She became immediately conscious and said she felt nothing. The suturing of the uterus and closing of the incision were absolutely painless. Testing the sensation with a pinprick, the patient was found analgetic up to and including the breasts. All the operations were completed in 40 minutes. Analgesia lasted 30 minutes after the patient returned to bed. This was a delayed case of anesthesia, showing that we should always wait 20 minutes for anesthesia. The patient vomited slightly and had profuse perspiration. Respirations were 28, pulse 120. There was no headache. During the administration of chloroform pulse fell from 110 to 60, became very irregular, then rose to 110 again and remained so.

	9 A.M.	9.15 A.M.	9.25 A.M.	9.30 A.M.	10 A.M.
Pupil.....	Normal.	Normal.	Normal.	Normal.	Normal.
Pulse.....	110	110	60 full, irregular	110	100
Respiration,	24	26	26 deep	26	24

The patient vomited slightly after going to the ward. There was no headaches at any time.

CASE 10.—R. J. F., aged 39, weight 165, was in good general condition. He was very nervous for fear of pain, every examination and manipulation heretofore having been extremely painful. Puncture was made at 3.27 P.M. between the fourth and fifth lumbar vertebrae. I injected 20 m. 2% cocain solution. Parathesia occurred in the lower extremities at 3.28, anesthesia at 3.30, extending as high as the axillae. The sphincter was dilated, and also a stricture of the sigmoid with absolutely no pain, and large tubes were passed without sensation. There was absence of sensation to heat

and cold; kneejerk reflex and ankle clonus were normal. At 3.25 the pulse was 26; respiration, 90; at 3.45 the pulse was 90, the respiration 28; at 3.55 the pulse was 90, the respiration 26; at 4.10 the pulse was 90, the respiration 26; at 4.35 the pulse was 90, the respiration 26. The parts were still completely anesthetic. The man then rose from the table and could walk to another room to dress; his gait was awkward and he seemed to walk on his heels; this seemed to tire him. After dressing he seemed to walk better, though somewhat shaky; at 5.15 feeling commenced to return slightly, and he left for home. He reported to me the following day saying sensation had fully returned at 7.30 the day before. At 7.45 he passed voluntarily about 8 ounces of urine; he had complete control of the bladder. He had very intense headache that night in the occipital temporal region. I had prepared him for this, having given him two tablets of $\frac{1}{16}$ gr. nitroglycerin. These had no effect; the headache had disappeared in 24 hours excepting a dull feeling about the forehead. He also felt drowsy during the entire day. Temperature was 98.8°; pulse, 72; respiration, 16.

The noticeable feature about this patient was the entire absence of all symptoms immediately after the injection. He only spoke of feeling warm. He also had slightly transitory nausea. He expressed himself as particularly pleased at the absence of all sensation and did not know when the surgeon had finished.

CASE 11.—J. P. was thin, anemic, and extremely hyperesthetic; his pulse was 114, and small. He had a supposed malignant growth of bladder. The patient could not endure two ounces of water injected into the bladder, because of unbearable discomfort. From his apparent bad condition it was not thought advisable to inject the usual amount of cocaine solution. Lumbar puncture was made between the fourth and fifth vertebrae, and cerebrospinal fluid was received into a sterile test-tube. I then injected not more than 10 m. of a 2% solution, without anesthesia; as it was too late the surgeon did not wish to have another injection on this day. The second day following I determined to use the regular quantity. Having carefully preserved the spinal fluid removed from him at the last puncture, I decided to make my cocaine solution with it instead of the plain water—this was first thoroughly boiled and then the cocaine added in the usual manner. The first puncture was between the third and fourth lumbar vertebrae on the right side. After the fluid dropped, pressure of the thumb was made to prevent undue loss. I injected 20 m. of a 2% solution of cocaine consuming 40 seconds in the injection. After 5 minutes the patient said his feet were asleep, he, however, was sensitive to pain up to 15 minutes. His feet up to the ankles were completely anesthetized. The abdomen was sensitive at 4.46 P.M. I made a second puncture between the fourth and fifth lumbar vertebrae of the left side. The fluid dropped slowly, only a few drops being lost. I injected 15 m. of a sterile 2% spinal-fluid solution of cocaine in about 30 seconds. Anesthesia occurred in 4 minutes, and quickly extended from the feet upward to the umbilicus. The patient said his entire legs were dead. No sensation to pinprick or knife existed from the feet upward to the axilla. The catheter was introduced and the bladder easily filled with 6 ounces of water without knowledge of the patient. At 4.59 the operation of epicystotomy was performed in the Trendelenburg position, with absolutely no evidence of pain or discomfort to the patient from opening of abdominal incision, to the suturing of the bladder and closing of the abdominal incision; during the suturing of the bladder the patient vomited and retched for 10 minutes, considerably interfering with suturing. The pulse was 120, the respirations 30. The patient was sweating profusely, without headache, the pupils were normal and he felt well though the pulse was small. Paresthesia existed in the hands though they were not anesthetic to a pin-prick. Anesthesia was complete to the axillae. At 5.30 the abdominal operation was finished. The operation of external urethrotomy was then done and the patient returned to bed at 6.10. At no time was the patient conscious of any pain or discomfort.

Puncture was made at 4.16, the operation done at 4.59,

and anesthesia, too, existed at the umbilicus at 5.02. At 5.05 $\frac{1}{4}$ grain of morphin was given hypodermically. The vomiting and retching lasted from 5.15 to 5.25.

The man was given whisky at 6.30, and the pulse improved; he said he felt well and had no headache. Anesthesia was still complete to the axillae. The pupils were decidedly contracted after the hypodermic of morphin.

CASE 12.—R. D., age 27, was plethoric, with temperature of 98.4, pulse 76, and respiration 16. The reflexes were normal. Whisky, 1 ounce, was given. Lumbar puncture was done at 8.30 A.M., between the fourth and fifth vertebrae, followed by the injection of 20 m. of 2% cocaine solution. There was paresthesia in the feet at 8.32, and at 8.35 extending to the waist; he was insensitive to pinprick. Operation was at 8.50,—dilation of the sphincter and removal of hemorrhoids by the clamp and cautery. The operation was finished at 9.10, when he was still anesthetic to the mid-chest. He was thirsty, had slight nausea, but no vomiting, and was perspiring profusely; at 9.50 sensation commenced to return, and at about 10.30 it was complete. Temperature the following day was 100, pulse 90, respiration 20, then returned to normal, without headache. The pupils were normal.

During anesthesia the following was the pulse-rate and respirations:

	8.40	8.50	9.00	9.15	9.30	10
Pulse.....	100	120	80	80	100	100 fall.
Respiration...	22	28	28	16	26	24

During the application of the cautery the patient felt the heat as warm, but had no pain at any time.

CASE 13.—M. B., age 31, was nervous and of a plethoric type. The operation was for closure of inguinal colostomy. An ounce of whisky was given at 3.25. Lumbar puncture was effected between the fourth and fifth vertebrae, followed by the injection of 20 m. of a 2% cocaine solution. At 3.30 she had a dead feeling in the feet, and was anesthetic to a pinprick. Operation was begun at 3.45. During the incision the patient apparently felt some pain; the rest of operation was done with no pain, though traction on the intestine caused nausea; resection and suturing of intestine caused no pain, though traction seemed to do so. Sensation to pinprick was abolished up to the lower rib. The patient occasionally looked at the operation; the sight of the scissors seemed to cause pain, whereas when her eyes were covered she had no such sensation. She seemed to feel traction of the intestine, and packing of the gauze; at the end of operation, 4.50, sensation had fully returned to the feet.

	3.30 P.M.	3.40 P.M.	3.50 P.M.	4.15 P.M.	4.30 P.M.	4.45 P.M.
Pulse.....	100	120	120	110	130	110
Respiration...	24	28	30	32	26	26

There was no headache the next day or at all. The pupils were at no time dilated.

CASE 14.—Mrs. F., aged 26, was stout, though pale, with pulse 90; respiration, 18. She had nephritis. Complete rupture of the perineum. One ounce of whisky was given, lumbar puncture was effected at 9.05 A.M., between the fourth and fifth vertebrae, followed by the injection of 20 m. 2% cocaine solution. There was no anesthesia in the feet at all or anywhere. After 15 minutes a second puncture with an injection of 15 m. between the third and fourth vertebrae on the left side was made, and likewise no result so far as anesthesia was concerned. She was perspiring freely, and the operation caused undoubted severe pain. I gave chloroform under which she did well. The pulse was 120 and small, falling to 90, and became quite full. She became conscious very quickly after chloroform was discontinued at 9.20.

	9.10 P.M.	9.20 P.M.	9.30 P.M.	9.40 P.M.	10.00 P.M.	10.15 P.M.	10.30 P.M.
Pulse.....	100	100	120	60	80	90	115
Respiration,	22	22	28	28	30	34	31

The pupils were normal throughout.

Fully one-half grain of cocaine was injected in this patient and produced absolutely no effect.

CASE 15.—A. S., aged 34 was somewhat anemic and of a very nervous temperament. The operation was to be closure of inguinal colostomy (the second case). One ounce of whisky was given, followed by the injection at 3.20 P.M. of

20 m. 2% cocain-solution. She immediately felt her feet dead; after lying down she was absolutely insensitive to pinprick up to the ankles; up to the hip, sensation was limited; after 18 minutes the operation was commenced. She seemed to feel slightly the incision, and fretted very much; testing the sensation, she was found to be painless, though she felt contact; no doubt when the operation was begun she seemed to feel the incision. A second puncture and injection was made at 3.40. Anesthesia did not extend. The patient was very nervous. Operation was continued and finished at 4.40. She seemed to feel traction on the intestines. Sensation to pinprick was felt as a dull pain, probably by contract simply. There was no headache. There was a slight feeling of nausea, though no retching, vomiting, or perspiration.

	3.30 P.M.	3.40 P.M.	3.50 P.M.	4.00 P.M.	4.15 P.M.	4.50 P.M.
Pulse	120	110	120	120	120	120
Respiration,	26	28	28	28	28	28

The surgeon told me he considered both these patients excessively nervous and more frightened than actually suffering.

CASE 16.—J. L., aged 59, a male of mid plethoric type, weighed 120. His general condition was good, his temperament sanguine, his respiration, temperature, tactile sense, reflexes, and pupils normal. Puncture was made at 2.00 P.M. between the fourth and fifth lumbar vertebrae, the fluid dropping slowly; only a few drops were permitted to be lost; a 20 m. 2% cocain solution was injected and the needle removed at 2.20. At first there was paresthesia, and complete anesthesia at 2.10. The operation was a femoral herniotomy with supposed tumor, which proved to be part of omentum incarcerated. Operation was begun at 2.15 and ended at 3.00. Anesthesia ended at 3.50. Five minutes after the injection, the pulse went up to 120, and ten minutes after fell to 60, then varied between 60 and 84, never going above 84. Respiration, five minutes after injection, was 30, then varied between 24 and 30. Respiration and pulse were taken every 5 minutes for one hour, then every 15 minutes for 3 hours following. There was slight nausea, but no vomiting; the following day slight headache and chill; pulse and respiration normal.

CASE 17.—R. C., aged 29, was of mid plethoric type. Her respiratory and circulatory system, pupils, temperature, tactile sense, reflexes, etc., were normal. One ounce of whisky was given. At 12.30 P.M. lumbar puncture was made between the fourth and fifth vertebrae, followed by the injection of 20 m. 2% solution of cocain. At 12.40 she had a dead feeling in the feet, and anesthesia was complete to the axillae at 12.43. The operation was a uterine dilation and curettage. It was commenced at 12.50 and finished at 1.10 P.M. The pupils were somewhat dilated, sensation to touch was present, but sensation to pain was absent entirely. There was no nausea or vomiting. I l ft at 1.45, when sensation above the umbilicus was returning. There was reaction to heat and cold, but no sensation to pressure. The vaginal and rectal sphincters were relaxed during the anesthesia. The pupils at times were normal, at others slightly dilated. The pulse varied from 100 to 60; at 1.30 it was 90. The respiration varied from 24 to 30; at 1.30 it was 26. At time of leaving the patient she said she felt good and coffee was given her. This patient had paresthesia in the arms and hands but was not anesthetic.

CASE 18.—G. K., aged 33, was anemic, but the general condition was fair. Pulse, respiration, temperature, pupils, tactile sense, reflexes, etc., were normal. One ounce of whisky was given. Lumbar puncture was effected between the fourth and fifth vertebrae. At 4.36 P.M. I injected 20 m. 2% cocain solution, the patient sitting on a chair; all he felt was warmth in the feet. When asked to sit on the table he found he could not do so, having no feeling in his legs; with help he mounted the table and was prepared for cystoscopy, which, as expressed by him when attempted previously, was torture. Sensation was tested and found absent to the umbilicus. A very satisfactory cystoscopy was performed, the patient being entirely oblivious to any pain. He vomited at 5.10, during which the rectal contents were forcibly expelled, the sphincter being relaxed. He could distinguish heat and cold but not pressure. Examination was finished at 5.30 P.M. During anesthesia the pupils were normal most of the time,

occasionally slightly dilated. The pulse varied between 120 and 100, the respiration varied between 28 and 18. At 6 P.M. he left the hospital, the pulse being 120, the respiration 18; the lower extremities still were anesthetic though he could walk very well, slowly. The day following he reported to me: he arrived home at 6.30; when testing sensations with pin he felt slightly. The pulse was 102 at 7.50, with marked chills and headache in the occipital region. I had given him powders of phenacetin 7 grs. and caffein citrate 2 grs., of which he took one and the headache became better. The chills did not last long. At 10.20 he was warm and perspiring, the pulse 100; headache was worse again in the morning; he took another powder and the headache was better except for a dull feeling; his headache was better when he kept perfectly quiet, if he but turned his head it became worse. He had also dull pain in the lower extremities. Pulse was 90 and full; respiration 18 and full; the temperature 99.2°. He spoke of the entire absence of pain during the examination the day before.

CASE 19.—Mrs. F., an anemic patient, had the spinal puncture injection about 10 days previously. Anesthesia was a failure in her case even after two injections of cocain aggregating over $\frac{1}{2}$ grain. The patient was hyper-sensitive. It was necessary to remove a broken glass catheter from the bladder, and remove the stitches of perineal operation. At 9.13 A.M. puncture was made between the fourth and fifth lumbar vertebrae; 20 m. of a 2% cocain solution were injected, followed by a dead feeling in the feet at 9.15. The feet were anesthetic to pinprick at 9.20, and anesthesia was as high as midway to the umbilicus. The patient was returned to the ward at 9.45 and complained of her feet still being dead. When sensation was tested with a sharp pin anesthesia was found still below the umbilicus. During manipulations the patient worried for fear she was to be operated upon, but it was evident, however, she felt no pain. Pulse was continually high from 120 to 130, and respiration from 24 to 36. The pupils were normal. At first there was pallor and then a suffused face. There was no nausea or vomiting up to 10 o'clock.

CASE 20.—The patient was of the plethoric type, muscular, and the pulse was 84, the respiration 20; temperature was normal. A half ounce of whisky was given at 2.23 P.M., and puncture made between the fourth and fifth lumbar vertebrae. I injected 20 m. of a 2% cocain solution at 2.25, followed by anesthesia to the ankles; at 2.30 anesthesia was complete to the axillae. The operation was an umbilical herniotomy and hysterectomy. It was begun at 2.40 and ended at 4.05 P.M. This patient felt the traction on the uterus and intestines; whether actual pain I am unable to state; there probably was pain during the pushing back of the intestines before suturing the abdominal wall. It is also supposed the patient saw part of the operation at one time and became excited over it. The first part of the operation was done with no evidence on the part of the patient of having felt anything. The anesthesia may have partly passed off toward the end, though before taking her to the ward I tested her sensations with a pin; she was anesthetic to the umbilicus. Her face was at first pale, then became suffused. Pulse after injection rose to 120, then varied between that and 60; at the end of the operation it was 102. Respiration varied from 20 to 30; the pupil at times was normal, sometimes slightly dilated. There was no nausea or vomiting up to the time she was taken to the ward.

In Case 11, but 10 minims were injected at the first puncture, and produced anesthesia almost entirely throughout the distribution of the small sciatic nerve on one side, that is, the posterior part of thigh and leg, from buttock down. This patient had a severe headache the entire day following. In Cases 6, 10, and 12, large plethoric types, 20 minims each were injected and produced surprisingly rapid and complete anesthesia. From these varying and interesting results, we must deduce that a quantity which in one patient will produce anesthesia, in another would result in failure, in others again resulting in but partial success. We cannot anticipate the necessary dose for the large and plethoric patients, as we have seen they are sometimes

easily influenced by small doses, whereas at times the small, thin, and anemic require large doses. We may formulate the only safe and practical plan to be used in all cases as follows: the intraspinal injection in any case should never exceed 20 minims of a 2% solution of cocain, or its equivalent. When this does not produce anesthesia, it neither affects the patient physiologically. At least this has been my experience up to the present time; a second injection may then be made with perfect safety. When the first injection has produced but partial anesthesia, the second injection should be made; this, however, less in quantity than the first.

DEDUCTIONS AND CONCLUSIONS.—The explanation of the failure to produce anesthesia in the first two cases, I believe, due to the large needles employed, the removal of which permitted the solution to eke out into the bony wall of the sacrum, exerting no influence upon the patient in any way whatsoever. In the other case, too small a dose, even after a second injection, though the first cases may have been due to this cause also. In the first patient, altogether $\frac{1}{2}$ grain was injected. The somewhat tense condition of the membranes of the cord and the entire absence of any symptoms would indicate that the explanation mentioned is the true one. The fact that Bier advises that the needle be not withdrawn for 2 minutes after injection would indicate the possibility of the loss of the solution before it disseminated in the subarachnoid fluid was not unknown to him. In the third case where a smaller needle was employed, anesthesia was complete from the middle of the thighs down; here a second injection would no doubt have produced complete anesthesia. This must be taken as a case of individual insusceptibility. It shows that cocain injected into the spinal canal differs in no way from its introduction into the general circulation, though I believe its symptoms are decidedly less developed by the spinal route.

I do not believe that the circulation is any factor in the production of anesthesia when cocain is injected into the subarachnoid space; its effects are in all probability due to the passage of the cocain from the subarachnoid space along the perivascular spaces in the tunica adventitia of the bloodvessels to the sensory columns of the cord, also directly into the lymph spaces of the nerves themselves, which have been shown by Key and Retzius to be continuous with the subarachnoid space.

Corning believed the circulation was the means of anesthetizing the cord, in corroboration of which he quotes Harley, from Ringer's work, to the effect that strychnin injected into the canal of the cord produced well-marked physiologic symptoms, but when placed in direct contact with the nervous elements of the cord divested of its vascular supply, the solution remains entirely inert. Hardly any other result could be expected to occur. If, however, the subarachnoid space and its fluid had been artificially replaced, his results would, in all probability, have been different. The physiologic symptoms, more or less produced in all patients, are probably due to the direct action of cocain upon the important centers of the cerebrospinal system and also, but to a lesser extent, the circulation. There is every reason to believe that the dilution of cocain by the cerebrospinal fluid is not great, as this fluid in any individual is very small in amount, though none the less of physiologic importance. The fluid is in greater amount in the region of the bulb, and its direct effect,

when containing cocain, upon the respiratory and vasomotor centers, can very easily account for the alteration in these functions, besides affecting the heart and respiration efferently through the sympathetic, which also accounts for the very profuse perspiration that frequently occurs. Hill has shown in his very perfect experiments that the cerebrospinal fluid-pressure never exceeds that of the cerebral veins, any tendency to increased pressure is counteracted by rapid absorption by the veins. It has also been shown that the cerebrospinal fluid when drawn off has a peculiar chemical composition, and is quickly, but how quickly he does not say, replaced by a fluid more similar to the serum. From what has been said, we may deduce that the cerebrospinal fluid is constantly though very slowly secreted and absorbed, and it is conceivable that the withdrawal of a small amount of the fluid may account for certain symptoms.

In Bier's experiment upon himself, he lost considerable subarachnoid fluid, developing well-marked, though not grave symptoms, which took him nine days to recover from. In his case it is reasonable to suppose the tension of the cerebrospinal fluid was lowered and reestablished only after some considerable time. It is also possible the rapid replacement of serum which is not at all like the cerebrospinal fluid may, though not probably in itself, be the cause of his symptoms.

The worst of all symptoms in many patients upon whom the lumbar puncture and injection have been made, is severe headache referred to the frontal, occipital, or temporal regions. This may be due to either an increased cerebrospinal fluid tension, though not probable, as any increased tension is quickly equalized by absorption into the veins. It may be due to decreased tension. This is, I think, the most important, though possibly not the only cause. It may also be due to the simple injection of sterile water or saline solution with or without cocain. As the cerebrospinal fluid is mostly secreted in the brain, absorption may also take place by this route, and the gradual elimination of cocain here may be the cause of the severe head symptoms encountered.

In Case 11, when the first puncture was made, the cerebrospinal fluid was permitted to drop into a sterile test-tube, and immediately plugged with sterile cotton. As another puncture was to be made upon this case, it occurred to me to make the cocain solution of this spinal fluid, which was done, taking the special precaution to boil this fluid thoroughly before introducing the cocain, exactly the same as when making a watery solution. If the headache complained of in this patient was due to the introduction of saline or sterile water or a reduction of cerebrospinal fluid tension, by replacing this fluid I might eliminate it; at the same time I might determine if cocain itself was the cause of the symptom. This patient had injected into the subarachnoid space the cerebrospinal fluid differing from his, normally, only in the addition of cocain. Again more fluid was injected than was lost by the puncture. This may have increased the tension slightly, but this, as we have seen, is of no consequence. The patient, in two injections received one-half grain of cocain and strange to say had absolutely *no sign of headache* at any time after the puncture. It may be contended that as some patients suffer from little or no headache these punctures may simply have acted in this manner. It is rather significant, however, that in the second punctures the total quantity of cocain injected was three times that of the first. I do not believe that the spinal fluid

solution of cocain will ever become popular, for unless the greatest precautions are taken, much harm may result, differing greatly in this respect from the water solution.

We must conclude from Bier's and my own experiences that the removal of the subarachnoid fluid should be restricted to the fewest drops; that is, after being certain that the needle is in the subarachnoid space (by a few drops of the clear fluid), the tip of the thumb should be placed over the end of the needle until the syringe is adjusted.

In conclusion, I would suggest that as the cerebral circulation is directly dependent upon the general circulation, a remedy for the headache may be found not in simple analgetics, but drugs exerting their influences upon the circulation direct either in an increase or decrease in the general blood-pressure. Increasing the blood-pressure favors an increased secretion of cerebrospinal fluid with an increased tension in the veins retarding absorption.

ANALGESIA IN OBSTETRICS PRODUCED BY MEDULLARY INJECTIONS OF COCAIN.*

By S. MARX, M.D.,
of New York.

In the development of any subject which opens up a new field of investigation, there will ever be on both sides of the conservative imaginary middle ground, those who are ultra enthusiastic, composed mainly of the pioneers in this new departure on one side, whilst on the other side are those who are hesitant, doubting, or absolutely pessimistic. This is the status which confronts us today in our position as advocates of cocain medullary narcosis. But is this not the history of all new departures in medicine? "Make haste slowly" will be our motto. Calm deliberation and time alone will tell the true story. Whether or not medullary narcosis will live and be useful, with a distinct field, limited or not, or whether through untimely mishaps, failures, or fatalities, the measure will be allowed to sink into innocuous desuetude the future alone can tell. Up to the present writing—and I speak from the obstetric standpoint alone—I am more than pleased; call it enthusiasm if you will, but this is not the enthusiasm of youth, nor that of the fervor of getting one's name associated with something new and startling; but the enthusiasm of success, calm, deliberate and painstaking after months of hard and trying work, with a record of success of which one need

not be ashamed. I write this not in a spirit of dogmatism or egotism, for I claim neither the honor nor do I wish it, since that crown of honor and success can only be given to Corning, of New York, before whom we bow our heads, and suppose that his not having pushed these measures more forcibly to the front in order to attain for them the recognition due, was because of his natural inherent modesty. But since this is always a measure of greatness we forgive and forget.

In obstetrics I have yet to record a failure, or even a bad result, whether attributable to the cocain or to the puncture itself. I shall refrain from touching on my experience in other cases, since these will be embodied in another paper later on. Up to the date of writing this paper, I have had over 40 cases of labor. Of these my first 6 cases were fully reported in the *Medical News* of August 25. My next paper in the *Medical Record* of October 6 of this year, gives the complete histories of 23 more. As my experience increases with this form of anesthesia in labor, my confidence in its application makes me more and more firm in the absolute utility and safety of its exhibition, and the best proof I can give of my sincerity in my statement is that I should not hesitate to employ this measure in my own family. I recognize but two dangers (1) sepsis, (2) cocain poisoning. 1. Sepsis can as surely be controlled in the lumber puncture as elsewhere in the body. I still maintain, that the surgically trained aseptic operator is the only one who can and will overcome this complication, and is the only one who should think of doing this otherwise safe operation. This territory is a dangerous one, and when we undertake to operate territory which is forbidden ground except for those who know how to be clean, we must surround our technic with every precaution tending to point in one direction—asepsis in everything and everybody directly or indirectly concerned around the operative field. In other words prepare the patient as if about to invade the abdominal cavity. 2. As to cocain poisoning, in all the cases reported there was at no time in any of my cases any symptoms which could be referred to cocain toxicity. In every case in which the puncture was made, there occurred certain symptoms more or less marked which might have been referred to the cocain. But how account in five cases that acted beautifully as central tests where the same symptoms arose and yet no cocain, or in one case an inert solution was used? And yet in these cases where either a saline solution or a solution of strychnin for purposes of inducing labor was employed by the intraspinal avenue, there were noted the headache, vomit, trembling of limbs, disturbance of temperature and pulse even as occurs after cocain, but minus the analgesia. Surely this is not sepsis, since it occurs in all the cases. And when with these symptoms there were found spastic contractions of the legs and the thighs, marked ankle-clonus, and a material increase of the patellar reflex, we have a symptom-complex present which denoted spinal shock or a condition due to disturbance of equilibrium inside the subarachnoid space. When cocain was employed the same conditions were present, plus an analgesia. But we are fully cognizant of the fact that poisoning may occur and has occurred. We are fully prepared to cope with it when the emergency arises, but I am thankful never to have met it. And I am of the opinion that cocain is particularly a safe drug in the parturient condition, and on the same grounds as chloroform. We know that there has never been an authentic case

* Read before the Obstetric Section of the New York Academy of Medicine.

of death from chloroform on record during labor. This for the reason that it is supposed to kill by causing an acute anemia of the brain. Pregnancy and the parturient state presuppose normally the opposite condition, viz., dilated cerebral capillaries, which means congestion, and thus in a measure the normal cerebral congestion counteracts any tendency to the pathologic anemia due to chloroform. Now, I think the dangerous symptoms from cocain are due to an acute anemia of the brain, whether proved other than clinically I am unable to state, which vicious action is aptly counteracted by the normal condition of that viscous, congested during labor, and thus any grave symptom is thoroughly antagonized. This may be the reason why I have never seen any symptoms which might be interpreted as due to cocain poisoning when administered during labor. Since my trials have commenced I have always felt that all the symptoms, so far as I know, were due to operative shock and not to cocain.

Technic.—From a greater experience I cannot find any improvement in the method which I have employed from the very beginning, since it has never failed me in reaching the canal in all my cases. The exaggerated inclined "searching position" is the one I prefer; and yet increased practice makes a right or left lateral decubitus as handy a position for me as the upright one, if only the back, it should be remembered, be arched by natural posture; or, by mechanical means, the patient's side in contact with a pillow is so raised as to give the spinal curvature a convex upwards; the natural posture being effected by placing head and pelvis on a level higher than the trunk, thus again bending the spine, but with the convexity downwards. I then inject from the convex side, for this has a tendency to increase the space between the individual vertebrae. *It is absolutely necessary for successful anesthesia to enter the spinal canal;* a *sina qua non* to an absolute analgesia is the escape of subarachnoid fluid before the cocain solution is injected, and by its escape I am in positive position to state that the needle is in the canal. There is no other guide. Since I have depended on getting a fluid tap I never failed to secure perfect anesthesia. This statement refers only to my obstetric work. In two gynecologic cases in spite of every step known to me for success, I failed. More of this later on.

As a rule the puncture is readily done, but in a few cases there has been the greatest difficulty in its performance, *i. e.*, in ankylosis of the spine; in an enormous fat back where I had to penetrate over two inches of fat before I reached the canal, and then had no needle left to enter the space; further, universal anasarca, where the edema of the back was so great that landmarks were utterly destroyed and the edema was so great that serum escaped from the needle, thus simulating the escape of spinal fluid. Only by placing the patient on the side was I able to get the needle into the canal, where after placing $\frac{1}{2}$ grain of cocain in the canal, as beautiful an anesthesia was produced as under chloroform. A total hysterectomy followed and was completed without pain.

The patient's back from coccyx to the middle of dorsal vertebrae is rendered sterile as is the abdomen before section. A finely tempered needle with as short a bevel, *i. e.*, point, as possible is employed,—length from 3 to 4 inches. I advocate a short bevel to insure as small a penetration as possible, for long needle points may wander beyond points of selection. In other words, as soon as I strike fluid, I want to check further penetra-

tion, and this cannot be satisfactorily nor safely done with the needles I have heretofore used, those with long points. The trocar point is the preferable one. I am still in favor of the solid hypodermic syringe, for it can be taken apart and boiled, there is no danger of breakage, nor are there washers to shrink. The one in present use and that one of my house-surgeon have been in use in all our punctures now over 100 times and still they are as good as new. The only advantage in favor of the glass syringe is that we can see and watch the fluid as it is injected.

Both needle and syringe are boiled for 10 minutes. The patient being placed in position, the thumb of the left hand is placed on the spinous process of the fifth lumbar vertebra. This point may be readily found by locating the deep depression between the spine of the fifth and first sacral, the posterior landmark of the external conjugate, or in very fat women, a line drawn joining the highest points of the crista illi will pass over the center of the fourth lumbar vertebra, and is a valuable guide. To insure absence of pain from the puncture through the skin a freezing spray is used. The needle is inserted in front of and just over the edge of the thumb at an angle of 165° , the direction being slightly from below upwards and from without inwards. If the point strikes the lamina it is to be moved gently up or down until the space between the vertebrae is felt, *i. e.*, absence of bony resistance; the point is pushed in very slowly and gently in a slightly downward direction until the clear, limpid fluid runs out. Immediately that fluid runs out the syringe is carefully screwed on, disturbing the needle as little as possible, and the cocain injected. From 8 to 15 m. (as the needle holds about 3 m., we must allow for this, and the barrel of the syringe charged with the extra amount) of a 2% cocain solution is used, representing between $\frac{1}{4}$ to $\frac{1}{2}$ gr. of the salt; the solution is slowly injected, the needle held in situ for a minute to plug the arachnoid puncture and insure the impossibility of its escape, and then withdrawn, and the puncture sealed. Within from 2 to 30 minutes anesthesia is ushered in, occurring somewhat suddenly, occasionally preceded by a marked hyperesthesia. There is often trembling of the limbs, and a feeling of formication in the effected areas. Vomiting often accompanies these symptoms, but is very evanescent. Operation can usually be commenced as soon as firm pinching or pulling upon the labia minora elicits no pain. If at the end of 15 minutes the desired result is not obtained, the injection may be repeated. In the light of our present experience small doses, say $\frac{1}{4}$ gr., give us sufficient anesthesia for any ordinary operation.

The area of anesthesia varies considerably and cannot be influenced by either the dose given or the force with which the solution is thrown in.¹ It depends upon the rapidity of absorption or on the susceptibility of the patient. I have seen analgesia from the ears down, but in most cases there is complete anesthesia from below the umbilicus. Anesthesia from one injection lasts from 1 to 5 hours. I have never noted any severe symptoms in labor, such as are occasionally seen in surgical work. There is no failing pulse, and never any cyanosis. In all our cases it was the rule to have disagreeable symptoms in all cases. But repeated trials by various drugs have given such excellent results that barring a very

¹ Pain to pinprick is absent. Sense of touch is retained to a gross degree, that is, the patient knows some object is brought in contact with the skin, whether brush or hand she cannot tell. In most cases heat and cold sense is retained, but is not painful. This has an important bearing in surgery, as for example in the use of the thermocautery.

short vomit and a transient headache I never see the distress I was formerly accustomed to.

After eliminating all drugs as inefficacious to combat symptoms, we pin our faith in three: (1) bromides; (2) hyoscin hydrobromate; (3) nitroglycerin. As a prophylactic measure it is very advisable to have the stomach of the patient empty for some time prior to the expected puncture, since I have noted a greater disposition to nausea and vomiting in patients who have recently ingested a full meal.

Since my belief has ever been that the symptoms immediately following puncture are due to some form of shock, my earliest and persistent endeavors were to find a drug which was a decided cerebral sedative, and to this end my best successes have been in those cases where from 30 to 40 grains of the bromide of soda was given from one to two hours before the expected puncture. Following this, and only in the event of the bromides failing, do I allow the administration of the hyoscin hydrobromate from $\frac{1}{10}$ to $\frac{1}{20}$ grain by the needle. To overcome all extra shock of pain the hypodermic should be given in the anesthetic areas. The nitroglycerin I usually reserve when slight cyanosis becomes apparent, or when the pulse fails; but the last indication seldom presents itself, for even though the pulse becomes feeble, rapid or slow, it is a sign that immediately anticipates the nausea and vomit, and is of no particular moment. Nitroglycerin is injected by the needle, from $\frac{1}{25}$ to $\frac{1}{100}$ grain.

Motor disturbances of the uterus I have never seen, for the uterine contractions go on regularly and rhythmically and under their action the os dilates as under normal conditions, and all this time, while the patient has some indescribable sensation in the abdomen, but not pain, she is delivering herself as naturally as if her symptoms of pain were not masked. Under these conditions we only recognize the powerful contraction either by placing the hand on the abdomen, or by exposing the protruding and bulging bag of water or the advancing head. Reflex action of the abdominal muscles was found present only when incomplete anesthesia existed, and was then accounted for by the presence of pain. But when anesthesia was complete, spontaneous bearing down did not occur; voluntarily the muscles were not called into play. Only when told to do so was the patient capable of bringing her abdominal muscles into play, and then as powerfully as under normal conditions. This I have always encouraged, to further the *vis a tergo* in normal labors. I have done some extremely difficult operations under spinal anesthesia, in fact all forms of obstetric operations were undertaken except symphysiotomy and cesarean section. Explorations, versions, forceps extractions, placental removals were done, not with as great ease as under chloroform, but with much greater facility than in a nonnarcotized (chloroform) woman. It was never necessary to finish any operation under a general anesthetic when commenced with medullary narcosis. Relaxation of the uterus or even spasm of severe grade was never encountered, nor was there a greater disposition to bleed than under ordinary conditions. My original indications (as given in the *Medical Record*) still are those I hold to day and from my present experience cannot be added to. I have carried a woman by repeated injections, for eight hours, through her labor with practically no pain. My rule at the hospital has been to inject when the pains begin to be severe. There is a distinct field when it becomes necessary to explore the pelvis for one reason or other. In very prolonged and painful first-stage labor, when it is

impossible for the doctor to sit for hours giving whiffs of chloroform, it would be ideal to give a cocaine puncture and relieve suffering for from one to five hours and yet have the labor go on and the os dilate painlessly.

Again, a case might be imagined in which both chloroform and ether are contraindicated, or a case in which no assistance is to be had and operating is absolutely imperative. A puncture is made, anesthesia is complete, and the operator can attend strictly to his field of operation. In cases of threatened or already present convulsions, in which a mere examination would provoke a spasm, a lumbar injection—lessening, as it does, peripheral nervous sensibility—might be of avail. But at best, so far as I am concerned, it is a method ideally suited to mitigate or absolutely allay the dreadful pains of a normal labor, with no danger to mother and none to child, immediate or remote.

One feature I have noticed—and it has been apparent to my guests witnessing the confinement—and this is the great ease with which I can dilate a cervix when the patient is cocaineized. The os seems to melt away from my fingers and its degree of dilation or its dilatability does not seem to be a deterrent factor for a rapid and easy manual dilation. It is not to be denied but that this form of narcosis will ever completely supersede general or cerebral anesthetization.

That one must expect failures cannot be denied also, and when failures occur they are as likely to happen under most humiliating circumstances. But there is no contraindication to follow up with chloroform. To my mind, a prolific source of apparent failure is due to the following inexcusable conditions, and it is one of the many links in the chain going to make this special form of anesthesia a complete and absolute success. The keynote is perfect quiet while operating. Sight and hearing are unusually acute in the woman. Apprehension is ever present, and a morbid fear that she might suffer pain causes not actual but psychical pain. This I have repeatedly demonstrated. To this end my audiences are told to refrain from talking, especially in reference to pain. The eyes of the patient are snugly bound and the ears are thoroughly plugged with cotton. No unusual bustle is allowed, and instruments are handled so as to insure absolute quiet. The operator gives his orders in an undertone, quiet and firm (what a blow to, and what an almost physical impossibility for the average operating surgeon!) The patient is constantly being reassured, her mind diverted by various measures—one patient was chewing ice while being operated upon, and interrogated by one person as to her sensations.²

ANESTHESIA IN CHILDREN WITH ADENOIDS, AND IN THE ADENOID OPERATION, WITH SPECIAL REFERENCE TO THE DANGERS OF CHLOROFORM IN CHILDREN OF THE LYMPHATIC DIATHESIS.*

By T. H. HALSTED, M.D.,

of Syracuse, N. Y.

Professor of Laryngology and Otology in the Syracuse University Medical College; Laryngologist and Otologist to St. Joseph's Hospital, and the Women and Children's Hospital.

THE presence of hypertrophied lymphoid tissue in the nasopharynx is often but a local expression of a general diathesis—the lymphatic diathesis—with which

*Table of cases sent by the author has been lost in transmission to us. [Editor PHILADELPHIA MEDICAL JOURNAL.]

*Read before the American Laryngological, Rhinological, and Otolological Society at Philadelphia, Pa., June 1, 1900.

the child is affected. Occurring during the immature and developing period of life, adenoids, by obstructing nasal respiration, impair the oxygenation of the blood and must of necessity affect injuriously, to some extent, every cell, every tissue, every organ of the body—not merely the neighboring organs of the ear, nose, and throat, but more remotely and yet certainly the heart, the lungs, the cerebrum, and every part of the body where blood circulates.

A child with adenoids, then, presents two distinct conditions, the lymphatic diathesis manifesting itself locally in the nasopharynx, and the constitutional and local results of nasal obstruction.

These children may be and often are of large build, weighing above normal, slow and sluggish both in their physical and mental activity, the word "flabby," perhaps, expressing their general physical make-up. There is another type, that of the nervous temperament, the children of this class being thin, peaked, hollow-eyed, restless, with the facial expression of mouth-breathing, and the dusky pallor of one starving for oxygen. On the other hand, apart from some local effect upon the ears, many are in apparent perfect health, until the obstruction is removed, when the child's general health improves so much that it is seen, by contrast, to have been in a worse general condition before the operation than had been suspected.

There is no question but that children with adenoids are in a depressed general health, and have weak hearts, impoverished blood, impaired lungs, and resist disease or shock with much less force than do other children. The recognition of the truth of what has been said is of vital importance, not alone to laryngologists and otologists, but to the general physician and surgeon, when he comes to the selection of a general anesthetic for children.

For many years—ever since chloroform and ether were discovered—it has been taught and thought to be true that chloroform was especially safe in children, and I dare say that 90% of medical men believe this to be true and act upon this belief. Those who operate much upon children are, from their individual experience, beginning to question this, and I believe that before many years are passed it will be recognized generally that chloroform is especially dangerous during the period of early childhood.

In a recent paper, discussing the selection of an anesthetic, Wyeth,¹ a general surgeon of wide experience, says that in about 75% of his operations in general surgery he uses chloroform in preference to ether, but states that in children under 12 years of age he considers chloroform especially dangerous and thinks ether should be the selective agent during this period of life. In children above 12 years of age, without any dyscrasia, heart-trouble, or kidney-lesion, he thinks chloroform as safe as ether.

With reference to the postmortem-findings in deaths occurring from chloroform, Kolisko,² who has probably made more autopsies than any other person, averaging 2,000 a year for many years, and of these about 6 a year on persons dying from cardiac syncope due to chloroform, in whom no previous lesion of the lungs, kidney or heart was known to exist, says: "In these cases we always find the condition known as the 'habitus lymphaticus.' The nature of this condition is (1) a persistent thymus gland which has often become considerably enlarged through an increase of its lymphatic tissue; (2) enlarged lymph-glands; (3)

adenoid vegetations in the pharynx, enlarged tonsils, enlarged follicles at the root of the tongue and in the pharynx; (4) enlarged follicles in the intestines and in the stomach. These conditions are accompanied by acute dilation of the heart, with no changes in the muscle or endocardium; or occasionally there is evidence of a previous cardiac dilation marked by thickenings in the endocardium, but not recognized clinically. There is also very frequently found a hyperplastic condition of the arterial system." Brickner, to whom this personal communication was made, adds, "It would seem, therefore, that in anesthetizing patients of the lymphatic temperament or those in whom there is a previous heart-disease, or in whom lymphatic enlargement or adenoid vegetations exist, chloroform should be rigidly excluded." That is to say, he would exclude chloroform not simply in the adenoid operation, but in any other operation in a child having adenoids, enlarged tonsils, or other evidence of the lymphatic diathesis.

Children have more fear and struggle against taking an anesthetic to a greater extent than do adults. Hare³ says, "Persons who are robust and strong, and who struggle violently are in greater danger from chloroform than the sickly and weak because the struggles exhaust the vasomotor system, strain the heart, and dilate the veins."

Chloroform, fear and shock are all strong cardiac depressants, any one of the three capable of producing death through cardiac syncope, and when all three are combined as is so often the case in anesthetizing frightened children, the patient is necessarily in a critical condition at the very beginning of anesthesia and this probably accounts for the fact that most deaths take place during this period and is also the most potent reason for never operating under primary chloroform-anesthesia, since in addition to the other three depressants you add another powerful one—pain. This is especially true in the operation for adenoids because here the anesthesia must be withdrawn before the operation is begun and the patient begins to recover before the cutting, which is done in an unusually sensitive site, is begun.

The explanation of Wyeth's clinical experience and belief that chloroform is especially dangerous under 12 years of age is, I think, to be found mainly in the fact that it is in this period of life that the so-called lymphatic diathesis is most marked, a much larger percentage of children than of adults presenting this condition. This, the lymphatic diathesis, together with the greater fear which children have of an anesthetic, would account for the statement that chloroform is especially dangerous during early childhood.

With reference now to the question of anesthesia in the operation for the removal of adenoids in children; time and clinical experience have proved that remnants of partially removed adenoids do not tend to shrivel and atrophy as was believed to be the case a few years ago, but instead show a marked tendency to enlarge and cause a recurrence of symptoms. A true recurrence of a completely removed adenoid is a rare occurrence, though one that does take place, but not with the frequency of a recurrence of symptoms. It is exceedingly difficult under any form of operation to make sure that all the growth is removed, but it is all important to remove it all. Thoroughness of operation is the most important consideration, and we must choose a method which permits of thoroughness with the greatest degree

of safety to the child and the infliction upon him of the least amount of pain, shock and hemorrhage both during and following the operation. The practice, prevailing in this country and Great Britain, of doing this operation on children under 12 years of age, under general anesthesia, is, I think, correct. Why children should be deprived of the blessing of narcosis in an operation which, above most others, is excruciatingly painful, and because of the great amount of blood, most horrifying and full of shock to sensitive children, is to my mind inconceivable, unless it be that the anesthetic offers so much more danger in this than in other operations. We know that in Germany and Austria it is the custom to operate without an anesthetic, but the operation, I am satisfied, is not only done very imperfectly and coarsely but too often brutally.

Two years ago, in one of the largest ear-clinics of Berlin, I saw a surgeon in the course of half an hour, while operating on 2 children about 5 years of age, without anesthesia, break and leave in the nasopharynx of each of them, the blade of the Beckman curet, at least half an inch in length. On the other hand, one of the most complete adenoid operations which I ever witnessed, was done 10 years ago, without an anesthetic by a justly famous German otologist, now dead, and it was done thoroughly and, leaving out the question of anesthesia, properly. The child was placed in an arm-chair on a raised platform. Straps in front of the legs, the thighs, the chest, forearms and arms and finally the forehead, bound the child to the chair. The little patient was completely and perfectly immobilized, mechanically anesthetized if you like. The operator then inserted the mouth gag, used the tongue depressor, introduced several times his forceps, removing the greater part of the growth. With different-sized curets and frequent examinations with the finger, all remnants were carefully cleared out. When the operation was completed to the satisfaction of the surgeon, the child was convinced that it had been thoroughly done. I assert that this is the only way in which this operation can be made on a small child with the proper degree of thoroughness, without using a general anesthetic, and I am satisfied that if all who operate without anesthesia would be as thorough, they would have a death-rate from shock approaching if not equalling that of those who use chloroform or ether.

Local anesthesia under cocain in small children is impracticable for the very good reason that, as used ordinarily, it does not anesthetize the deeper parts where cutting is done, and if applied deeply with the hypodermic needle it would be attended with more fatalities than chloroform. In many children above 12 and 15, and in adults, the operation may be done under cocain, although almost never without a great amount of pain. Persons of this age commonly prefer, however, to stand the pain to taking a general anesthetic, and, if necessary, several operations at different times may be made. Cocain is not without danger. Sanford⁴ reported a death from cocain in this operation, and in the discussion of his case 2 others were reported. How many more have not been recorded is not known, but probably few attempt its use with a view to getting genuine anesthesia in small children.

Chloroform is probably the agent most commonly employed today in the removal of adenoids, though many operators are giving up its use and employing ether, ethyl bromid, or nitrous-oxid gas. Fatalities will occur with any of them or without any of them,

but we are bound to choose that one which is least likely to kill and at the same time permit of a proper operation.

Hinkel,⁵ in a strong paper in 1898, called attention to the high mortality from chloroform in this operation. He was able to find in this country the reports of but 3 fatal cases besides his own, while in England during the preceding 5 years, 14 cases were recorded. In both countries but 1 death from ether was reported. Since that time, *i. e.*, in the past 2 years, I have been unable to find the report of but 1 death due to chloroform or ether in the adenoid operation occurring in this or any other country. This was a death from chloroform reported by Wishart.⁶ Until I had the misfortune nearly 2 years ago to lose a patient, 10 years of age, the heart ceasing and breathing stopping a few minutes after the adenoids and tonsils were removed and chloroform taken away, I fancied chloroform was, all things considered, as safe as ether.

The sooner we recognize and realize the fact that statistics relating to the frequency of deaths from chloroform and ether, especially if based upon reports found in medical journals, are utterly valueless, the better off we shall be. Such statistics prove only that physicians will report anything rather than a fatality from any anesthetic. I myself know, or have learned through verbal communication, of more chloroform fatalities in the adenoid operation than are recorded in all American medical journals. So far as they go, however, statistics are overwhelmingly in favor of the view that chloroform has caused in the removal of adenoids many more deaths than ether, but, on the other hand, chloroform has undoubtedly been employed many times as often as ether, so that we cannot altogether rely on statistics until they approach a semblance of accuracy.

In the earlier part of this paper I believe I showed clearly that chloroform is proved to be theoretically, clinically, and by postmortem findings, the one drug from which in this operation we ought to expect a high mortality. It ought to have a higher mortality in this than in other operations if Kolisko's investigations mean anything, because the lymphatic diathesis is here nearly always present.

With ethyl bromid I have had no personal experience, being prejudiced against its use because of the fatalities in other operations which have been reported with such frequency that it is proved to be not the harmless agent we were at first led to hope it might be. When it kills, it kills quickly, very much like chloroform, being a powerful cardiac depressant; and in children who are of the lymphatic diathesis and depreciated in health and tone by mouth-breathing, I should feel that the objections that exist to the other would exist to this newer anesthetic.

Nitrous-oxid gas I have used a few times and have seen others operate for adenoids under it, but not to my satisfaction excepting in exceptional circumstances. The patient recovers too rapidly to permit of a thorough operation, especially if one does the double operation of adenoid and tonsils as I am in the habit of doing when, for in the majority of cases, all require removal. At the same time there are many cases in which nitrous-oxid gas would be sufficient, and it probably has a valuable place as a preliminary to etherization, though I have had no experience with it in this connection.

In the great majority of cases, all things considered, I believe ether is the best anesthetic for the adenoid

and tonsil operation, and in children with adenoids should be preferred to chloroform in other operations. I have employed it almost exclusively in this operation for the past 18 months and for 8 years prior to that very many times. I am well aware that in this operation ether presents many peculiar disadvantages. As compared with chloroform the patient is longer in becoming unconscious. There is more suffocation and struggling; retching and vomiting are always possible complications and of more importance in this than in most short operations on other parts of the body. The operation is unquestionably attended with more hemorrhage than when chloroform is used, and because of the retching there is more danger of the blood and stomach-contents being aspirated into the lungs, or of the blood and mucus being churned into a semisolid mass in the to-and-fro movements of respiration. The special dangers to be apprehended then from ether are those of asphyxia, and if death should occur it would come on comparatively slowly and not until a great deal, including tracheotomy, had been done to avert it, greatly differing from chloroform, which, when it causes death, does so without warning and almost instantaneously.

Primary ether-anesthesia in a short operation, not complicated by enlarged tonsils, is often sufficient and there is not the objection to it that exists to chloroform in the primary stage, ether being a cardiac stimulant which would offset the depressant effects upon the heart of shock and pain that might occur before the completion of the operation. In primary ether-anesthesia the patient does not recover from the anesthetic nearly so quickly as from chloroform in the same stage, so that one has a much longer time to operate. In longer operations, when both adenoids and tonsils are to be removed, the third stage may have to be reached, but expertness in operating will make the primary stage very often all that is necessary even when both adenoids and tonsils have to be removed. Expertness in operating should be cultivated because the shorter the operation compatible with thoroughness the better for the patient, since the danger of blood entering the trachea and asphyxiating him is lessened.

Objectors to ether emphasize the serious after-effects upon the lungs and kidneys. As these depend upon the quantity of ether inhaled, they are not to be feared in the operation under consideration because of the shortness of the operation and the comparatively little ether inhaled.

The disadvantages of ether can be largely overcome or much minimized. The art of giving ether has been much neglected in the teaching of medical schools, so that it is very commonly given, indifferently or badly. The saying that few can give chloroform safely, but that anyone can give ether, is one of those loose statements that cause positive injury in that it prevents men from appreciating the necessity of learning the art of etherization, and it is an art. For the past year I have had atropia, in doses of $\frac{1}{300}$ to $\frac{1}{100}$ grain, depending on the age of the child, given hypodermically prior to the ether. This so greatly diminishes the excessive secretion of mucus in the pharynx, trachea, and bronchi that it largely overcomes this objection to the employment of ether.

Rosenberg¹ and Laborde have advanced the theory that the nausea and vomiting resulting from the inhalation of ether and chloroform is produced by the irrita-

tion of these drugs upon the peripheral branches of the trigeminal nerves in the nasal mucous membrane. This irritation of the trigeminals causes a reflex stimulation of the pneumogastric and inhibitory respiratory center in the medulla, with the result that nausea and vomiting are produced and struggling and a feeling of suffocation excited. Now, if to the nasal mucous membrane cocain in a 5% to 10% solution is applied, the nerve endings are deadened and consequently less stimulation of the pneumogastric and inhibitory respiratory center follows. They advised that cocain be sprayed into the nose some minutes prior to beginning the anesthetic and in long operations reapplied by spraying. I have for six months or more made use of this suggestion in many of my operations when ether is given, never, however, spraying the cocain, but applying it by means of a cotton swab, dipped into a 5% or 10% solution, depending upon the age of the patient, and making use of but 2 or 3 drops, and then gently and rapidly inserting the small swab into each nasal cavity, and brushing over the mucous membrane. By this means a very small amount of cocain is used, never enough to excite any apprehension from the effects of the cocain. My experience with this has been so satisfactory that I mention it here, feeling that it does much to overcome, or at least diminish, one of the great objections and one of the chief dangers of ether, that is the vomiting and inhalation or aspiration into the lungs of stomach-contents or blood. Given a good anesthetist, atropia hypodermically and a very small amount of cocain applied to the nasal mucous membrane, ether is as readily administered as is chloroform and with but a fraction of the danger.

In conclusion:

1. Children with adenoids present two distinct conditions, viz., the lymphatic diathesis, manifesting itself locally in the nasopharynx, and the constitutional and local effects of mouth-breathing.
2. Mouth-breathing children and those of the lymphatic diathesis are in depressed general health and possess a lowered general tone of all the cells and organs of the body and so resist badly all heart depressants, such as chloroform, shock, fright, etc.
3. Instead of being regarded as comparatively safe in children, chloroform should be especially feared during the period of childhood because of the existence, among so many children, of the lymphatic diathesis; the presence of this diathesis is a positive contraindication to the use of chloroform in any operation.
4. The adenoid operation in children under 12 years of age without general anesthesia must as a rule be condemned because it does not permit of a thorough removal of the growths, is exceedingly painful, and because the pain and loss of blood produce such shock that irreparable injury is often done to the nervous system of a sensitive child.
5. For the removal of adenoids, ether properly administered is incomparably safer than chloroform and in skilled hands is but little more disagreeable to the patient, and in the great majority of cases is the best anesthetic in this operation.

LARGE SCROTAL HERNIA: OPERATION FOR RADICAL CURE UNDER SPINAL ANESTHESIA WITH EUCAIN; ALUMINUM BRONZE WIRE USED FOR BURIED SUTURES: OPERATIVE RECOVERY; DEATH FROM EXHAUSTION AND URINARY SEPSIS.¹

By W. W. KEEN, M.D.,
of Philadelphia.

W. W., aged 51, was sent to the Jefferson Medical College Hospital by Dr. E. N. Moyer, Jr., of Greenville, N. C., September 13, 1900. He was a negro farmer. His mother and father and two brothers died of causes unknown. He has one brother and three sisters living, and in good health. There is nothing else in his family or personal history which would bear upon his disease. He denies syphilis, but admits gonorrhea in 1896.

In 1877, while working in a ditch, two small lumps suddenly appeared, one in each groin. He states that they were not painful. The one on the right side disappeared in 1880, while the one on the left continued steadily to grow in size. He also states that last summer the tumor on the right side reappeared, and then disappeared 2 weeks later.

On examination, a large, left-sided, scrotal hernia was discovered, the scrotum extending nearly to the knees. The ring is so large that four fingers can be inserted into it without trouble. The hernia can be reduced with moderate ease, but the abdomen, which, prior to the return of the hernia, is scaphoid, then becomes arched, very tense, and he has a great deal of discomfort, especially in breathing.

The urine was of specific gravity 1.012, acid, contained a small amount of albumin, no sugar; urea 13%; no casts were found, but there were numerous leukocytes, and a few red blood-corpuscles.

Operation October 3. The usual Bassini operation for the radical cure of the inguinal hernia was done under spinal anesthesia by eucain.

During the operation, Dr. Wiggins, one of the anesthetists, made the following observations on his pulse, respiration, and temperature. Unfortunately, I did not take the pulse, respiration, and temperature immediately before injecting the eucain; but the observation, 2 minutes later, was probably the same. The temperature was taken under the tongue.

HOUR.	PULSE.	TEMP.	RESP.	REMARKS.
2.03				One ccm. 2% eucain injected between the third and fourth lumbar vertebrae.
2.05	80	96.3 ²	18	
2.10	120	96	—	Sensation persists in legs and feet, operation begun. An incision 15 cm. long was made over the upper scrotum and extended nearly to the anterior superior spine. No pain was felt and yet at the same time a prick of the needle at his ankle made him jerk his legs.
2.14				
2.15	120	96	—	
2.20	120	96.1		Prick in the ankle still felt; slight headache.
2.23				Felt a warm salt-solution poured over the bowel.
2.25	122	96.2	20	As the bowels were being restored to the abdomen, a process which took considerable time, he said that he felt a little pain, but did not manifest it by any motion.
2.30	126	96.2		Pulse weak.
2.35	98	96		Some nausea soon followed by vomiting. As the pulse was weak one-twentieth grain of strychnin was injected hypodermatically, and 2 drams of brandy given by the mouth.
2.40	68	96.2		
2.45	100	96.2		Nausea all gone, pulse very distinct, entirely comfortable, though he still felt a pin-prick in the ankle.
2.50	78	96		
2.55	82	96	30	Pulse fair.
2.58				Operation completed, patient comfortable.
3.00	92	96.4	22	General condition good; pupils were contracted during the operation.

From the surgical point of view it is to be noted in addition that the scrotum contained not only a large portion of small intestine, but about half of the colon, including the caput coli and the appendix. If, therefore, he had suffered from appendicitis, it would have been a left-sided scrotal attack. As the appendix was healthy and I had

enough on hand, I left it alone. The ordinary Bassini operation was then done with interrupted sutures instead of continuous, and I used aluminum bronze wire to unite the muscular layers, continuous silk for the external oblique and interrupted silkworm-gut for the skin.

His temperature rose on the day after the operation to 101°, but fell on the next day to 100°, and fluctuated between the normal and 100° until the twelfth day after the operation. At the end of a week the wound was entirely well and the stitches all removed. Two days after the operation, as he required to be catheterized, it was discovered that he had so tight a stricture that only a filiform bougie could be introduced. The stricture was dilated by Prof. Horwitz up to a No. 19. The urine, however, became increasingly turbid, though every possible antiseptic remedy was used, and on the twelfth day (October 15) the temperature rose to 101.6°, and thereafter fluctuated between that and a somewhat sub-normal temperature. He rapidly lost ground, especially as to his strength, and succumbed to exhaustion on October 21, 18 days after the operation.

Remarks.—Spinal anesthesia has passed through two stages. An intermediate but necessary step between the two stages was a purely surgical one, irrespective of any reference to anesthesia. The first step was taken in 1885 when J. Leonard Corning of New York injected both in experiments on the lower animals and later in a number of cases in man, a solution of cocain, not into the spinal cord, but into the tissues just outside of it. In this way he showed that the veins carried the solution to the cord and produced an anesthesia below the point at which the injection was made.

It is not at all impossible that with increasing knowledge of the subject we may again revert to this method at points at which it is not permissible, nor, in some cases, physically possible to puncture the spinal canal.

The intermediate step was Quincke's lumbar puncture.

The second step was taken by Bier in 1899, without any knowledge, it would appear, of Corning's work. He based his experiments on Quincke's lumbar puncture (with which, of course, he was more than familiar, as both of them were in the Faculty at Kiel), and he conceived the idea of injecting the cocain directly into the spinal canal.

The method, therefore, it seems to me, should be called the "Corning-Bier method," provided any personal name is given to it. It would not be just to call it the "Bier method" alone, since the essential principle of the procedure was thought out by Corning, nor would it be just to call it the "Corning" method, since Bier's improvements are essential and also original.

The introduction of lumbar puncture led by a natural step to the method advocated by Bier. This is a difference of mechanical technic, and a very important one, but the credit of first proposing the basal principle of the whole procedure, namely,—cocainization of the spinal cord—belongs to Corning.

The site selected should be the lumbar region below the termination of the cord, so that no injury shall be done to the cord itself, especially its lumbar enlargement. In fact, it is a question in my mind whether the action of cocain or eucain, when applied directly to the delicate fibers of the central nervous system, may not prove occasionally, and, possibly, more than occasionally, deleterious. Until the nerves leave the dura mater through the intervertebral foramina, they are without any sheath, hence the anesthetic being injected into the cerebrospinal fluid attacks the nerves very much more readily than if they were protected by a fibrous sheath.

¹ Presented as a verbal communication to the College of Physicians, October 3, 1900.

The technic of lumbar puncture is a very simple one. The level at which the injection is made is the level of the crest of the ilium, *i. e.*, just above or below the fourth lumbar vertebra. As soon as the cerebrospinal fluid escapes, we know that the needle is in the canal, and the injection (1 ccm. of a 2% solution) may be made. It should not be made until this phenomenon, *viz.*, the escape of the cerebrospinal fluid, is observed. Anesthesia up to the level even of the diaphragm, and if larger doses are given, somewhat higher sets in in the course of 6 or 10 minutes, when the operation may be begun. In the case herewith reported it was certainly very curious that the patient did not feel the pain of the operation in the inguinal region, yet he jumped sharply when he received a needle-prick at the ankles. This observation was confirmed by two subsequent similar observations.

I used the method of spinal anesthesia in this particular case for two reasons; first, the man had bad kidneys from an old neglected, and, at the same time to me unknown, stricture of the urethra, followed by cystitis and albuminuria. It was my opinion that the spinal anesthesia would not have any deleterious influence on his kidneys, whereas chloroform or ether might do so. But the principal controlling motive in using it in this case was that fully half of the intestines had lost what the French picturesquely call their *droit de domicile* in the abdomen. They had been in the scrotum for 27 years. They could be restored to the abdominal cavity, but produced a considerable embarrassment of respiration, and if this restoration was accomplished during profound anesthesia, I was by no means sure but that there would be a possible danger even to life by the encroachment on the lungs through pushing up of the diaphragm as a consequence of suddenly doubling the contents of the abdomen. If the patient were conscious and the discomfort had become marked, then I should have re-established the hernia. Under general anesthesia, however, this embarrassment of the respiration might have readily gone on and escaped observation until too late.

I used eucain and was well satisfied with it, though Murphy and others who have used the method in this country before myself, have tested it and did not approve of it. Eucain is less toxic than cocain and can be boiled and, therefore, readily disinfected. Cocain cannot be brought above 80° C., without destructive effects, and in the hands of a careless person, the thorough method of Tuffier of a six-fold heating to this temperature may be very easily neglected and sepsis readily induced. In fact, the chief danger of the method, in my opinion, is the danger of an imperfect asepsis; hence I believe that it is a method not to be used by everybody, but only by competent, skilled, and careful surgeons. Nor do I believe it will ever replace chloroform or ether as a routine anesthetic. Its use will be only an occasional, possibly even a frequent one, in selected cases. I proposed using the method in a patient upon whom I did a total hysterectomy a few days later, for the reason that a year ago I had removed one of her kidneys, and I did not like to risk the effect of ether or chloroform on the single remaining kidney; but her fear of lying conscious for so long a time as the operation of hysterectomy would require, and the consequent strain upon her nervous system, caused her to prefer to run the risk of the kidney rather than the risk of the mental strain.

This is by no means one of the smallest objections to

the method. The ideal anesthetic, as I have several times pointed out in other papers, is not an anesthetic which abolishes sensation, leaving consciousness intact, but an anesthetic which will abolish consciousness and, therefore, sensation, *without the slightest danger to life.*

I had every reason to be perfectly satisfied with the action of the anesthetic in this case. The anesthesia lasted about an hour. At the end of a week the wound was entirely well, and everything seemed to be progressing favorably. The urinary symptoms, however, then came to the fore, since two days after the operation a very tight stricture was discovered, of the existence of which he had not previously complained. He died as a result of a neglected stricture, and not at all as a result of the spinal anesthesia.

ANESTHESIA BY COCAINIZATION OF THE SPINAL CORD.

By GEORGE G. HOPKINS, A.M., M.D.,
of Brooklyn, N. Y.

ANESTHESIA by cocaineization of the spinal cord, or, as it has been called, medullary narcosis, while not the device of a French brain, has nevertheless derived its present general notoriety from the indefatigable and painstaking labors of Professor Tuffier, of Paris. The invention of a German was developed by a Frenchman, and carried to a perfection that has rendered this use of a dangerous and uncertain drug as safe as many other forms of anesthesia which are countenanced by the profession. Since Tuffier published his results in the use of this drug, it is claimed that the method originated in this country. Be that as it may, it was a dead method until brought to light again by Tuffier and perfected in the manner of administration. It has attained its world-wide notoriety owing to his operations during the session of the Thirteenth International Congress at Paris in the summer just past. At these sessions he courteously explained his method of procedure to every one of the visiting thousands who had been fortunate enough to learn when and where his clinics were to be held. To me it opened a new light in the world of anesthesia. The first application of this method is a surprise and a revelation. To be able to converse with a patient during the performance of a hysterectomy or other major operation, the patient all the while evincing not the slightest indication of pain (and even being unable to tell where the knife was being applied), was certainly a marvel, and was well worth crossing the Atlantic to see. Still, although this effect is plain, we have yet to determine the safety of the method, not only in its immediate results, but in its ultimate effect upon the nervous centers. The method so impressed me that I put it into operation in September last. I have collected in this brief time the reports of 225 cases. Of these 222 are reported as having been successful. In two there was depression and life was threatened.

In the first case of these last two with unsatisfactory results, anesthesia was produced, but depression and the poisonous effects of the drug were perceptible and active for six hours. In the second, a case in my own hands, all the symptoms of acute cocaine poisoning were developed. Yet in this case I got a clear arachnoid fluid from the canula after introduction of the needle into the lumbar space, which proved conclusively that we

had punctured the sac. In this case I injected 30 minims of a fresh thoroughly sterilized 2% solution of cocain. (I never use a solution after it is 48 hours old.) At the end of 10 minutes there was not the slightest anesthetic effect produced on any of the nerves of sensation, but the patient was trembling from head to foot and the pulse was somewhat feeble.

Tuffier claimed that ether was not contraindicated when cocain did not produce the desired effect. I therefore proceeded to have ether administered. The patient quieted down under it and I began my operation. My anesthetist notified me that the patient was in a bad condition and the operation was suspended and we turned our attention to resuscitation. The effect of the ether soon passed off and the patient regained consciousness, but her general condition was very alarming, the pulse being 160, respiration feeble, the pupils dilated, and general tremulousness of the whole body, with considerable vomiting. At times the heart almost stopped. We injected three pints of saline solution in the brachial vein, and two quarts in the rectum, and administered strychnin and nitroglycerin hypodermically. With all these measures it was six hours before we were at all relieved about the immediate condition of this patient. Her pulse continued rapid and she had frequent "sinking turns" for the next ten days, with general depression and great tremulousness of the whole muscular system.

When medullary narcosis is complete and safe, as it usually is, there is a sense of relief in operating that one does not always feel with a patient under the influence of an anesthetic that produces cerebral anesthesia.

The sphincter ani is the last muscle to relax under ether or chloroform-anesthesia, yet I have stretched the anus with the patient under cocain, injected into the cord, without the least consciousness on her part of what was being done.

The process of anesthetization by this method is certainly very remarkable and has many useful applications, but we have yet to perfect the method and above all to find a reliable guard to its poisonous effect. There are hundreds of patients being anesthetized with cocain all over the world, but it is very difficult to get at the complete statistics, as we are all of us more ready to report our successes than our failures.

It is very important that every patient whose spine has been injected with cocain should be kept under observation for a year or more in order that the profession may ascertain whether interference with such a cavity as the spinal canal, carrying as it does the cord, the integrity of which is so important to the functions of life, shall result in disease of the nerve centers or of any special nerve function. Neuroses are very insidious, tardy in their approach, and do not make themselves felt until some time after the exciting cause has ceased to act.

These are considerations that we should bear in mind when making use of this wonderful method of producing anesthesia.

The use of this procedure must not be undertaken by any surgeon without the most careful sterilization of the fluid to be injected and the most scrupulous cleansing of the surface of the back all about the region where the injection is to be made. The slightest deviation from the most rigid antiseptic precautions, when invading such an important vital center as the spinal canal, is criminal.

Dr. Tuffier has devised a syringe for the injection of

the cocain into the spinal sac. The syringe is glass. The needle is platinum and beveled at the end so as to make a cutting point, for introduction through the skin. It is 3½ inches in length and has bent in my hands when trying to pass it through a tough skin, which is the only tissue that offers any serious resistance if the needle is carried in a proper course.

I have had Tiemann & Co. make me a trocar and canula of the same size as that of Prof. Tuffier's, which is more convenient of introduction. When you have passed in between the laminae of the fourth and fifth lumbar vertebrae the trocar may be withdrawn, and if there is no return of the clear limpid spinal fluid, it should be reintroduced and passed further on, and the operation repeated until the sac is punctured. The trocar has the additional advantage of keeping the canula patulous, since not infrequently the operator may puncture a bloodvessel before reaching the spinal canal, and thus gets a flow of blood from the needle; this may clog it, and requires its removal and reintroduction.

SUBARACHNOIDEAN INJECTIONS OF COCAIN AS A SUBSTITUTE FOR GENERAL ANESTHESIA IN OPERATIONS BELOW THE DIAPHRAGM. WITH REPORT OF SEVEN CASES.

By EDWARD WALLACE LEE, M.D.,

of St. Louis, Mo., formerly of Omaha, Neb.

Member of American Medical Association, the Mississippi Valley Medical Association, etc.

THIS method of anesthesia, originally instituted by J. Leonard Corning, subsequently adopted by Oberst and Bier, and lately brought to greater perfection by Tuffier, of Paris, and Murphy, of Chicago, is a procedure which demands the most scrutinizing investigation on the part of every one interested in the subject of anesthesia. The results obtained, though not free from difficulties and objections, are sufficient to warrant and call for further investigation. From data collected there is reason to believe that 1800 operations have been performed without a single death having to be recorded, and with no unfavorable complications or symptoms, except such as can be avoided if proper precautions are used.

It is stated that in many cases after this procedure a rise of temperature has been noted without complications directly due to the operation. From my observations I am inclined to think that this is merely the post-operative rise of temperature which is usually observed. The unfavorable complications or symptoms which follow the subarachnoidean injection of cocain are nausea, headache, general nervousness, and expression of anxiety, and general prostration with a tendency to collapse. Another disagreeable feature is the pain and inconvenience complained of by the patient as a consequence of the puncture. This latter operation, I believe, as the result of my observations, can be overcome by first producing local anesthesia, with ethyl chlorid, of the spot to be punctured. A hypodermic injection of $\frac{1}{30}$ of a grain of strychnia, $\frac{1}{150}$ grain of atropin and $\frac{1}{6}$ of a grain of morphia will, to a great extent, mitigate the unfavorable symptoms alluded to.

The operative technic of the procedure, as followed by Tuffier and Murphy, is about as follows: The field of the injection is first thoroughly aseptized. Then, having located the iliac crests, one finds a line connect-

ing these two crests and passing through the fourth lumbar vertebra. Injecting beneath this line, the medullary canal is punctured. In order to locate this position exactly, the patient must be instructed to bend forward so as to produce as nearly as possible a right angle of the lumbar region with the pelvis. This bending forwards separates the lumbar vertebra, causing a separation of 1.5 cm., and allowing sufficient space for the injection. Make the injection with the right hand, and insert the needle to the right of the vertebral column, about 1 cm. from the line of the spinous process.

It is well to know what structures the needle passes through. They are the skin, subcutaneous cellular tissue, lumbar aponeurosis, muscles of the sacrolumbar region. Having gone through these, the needle penetrates the lamellar space, and at last enters the spinal canal. As soon as this point is reached, the needle meets with no resistance. At the same time there escapes from the needle, drop by drop, a clear, yellow fluid. This is a cerebral spinal fluid, and the cocaine-solution should never be injected until the surgeon has observed the escape of this fluid. After the fluid has escaped, the injection should be made. The injection which I have used is from 12 to 20 minims of a 2% sterilized solution, put up in hermetically sealed tubes by Truax, Green & Co., of Chicago, and I have made the injections with a syringe with a platinum needle also made by them. The solution is injected slowly. It takes from 4 to 12 minutes for the anesthetic condition to become apparent. It lasts from 20 minutes to an hour and a quarter.

Up to date the following cases represent my experience of producing local anesthesia by the method described:

CASE 1.—Girl, aged 9, with tuberculous necrosis of the tibia; 12 minims of a 2% solution were injected 8 minutes before operation was commenced. This lasted 30 minutes. There was no nausea, no headache, no symptoms of shock or collapse.

CASE 2 was one of internal hemorrhoids, in a male patient, 22 years old. The injection was 15 minims, 7 minutes before operation was commenced. Pain was felt on attempt being made to dilate the sphincter ani, but no pain on applying ligatures and removing hemorrhoids. The operation lasted 20 minutes with no unfavorable symptoms.

CASE 3 was one of epithelioma of the cervix, in a woman aged 38. Operation was begun in 6 minutes. The quantity used was 15 minims. The cervix amputated, the patient experiencing no pain or unfavorable symptoms.

CASE 4.—The operation was for hemorrhoids in a male, aged 39, a strong robust man. Amount of anesthetic was 20 minims, with 20 minutes of waiting before commencing operation. The sphincter was dilated readily without pain. There was slight nausea and headache, but no other unfavorable symptoms.

CASE 5.—The operation was in a male, aged 62, for suprapubic cystotomy for drainage from an enlarged prostate. Amount of anesthetic was 10 minims. The patient suffered slight nausea after operation as well as some pain during it. This case I consider extremely favorable, as any other form of anesthetic would, I believe, have been attended with severe symptoms. The time of operation was 10 minutes.

CASE 6.—The patient was a male, aged 32. The amount of solution, 12 minims. The time of operation, 30 minutes. I everted the inguinal glands, with no unfavorable symptoms.

CASE 7.—The man was aged 28. The amount of anesthetic was 20 minims, the length of operation (Bassini) was 20 minutes; it was for uncomplicated inguinal hernia.

Preceding all these operations, a hypodermic injection of $\frac{1}{2}$ of a grain of strychnin, $\frac{1}{16}$ of a grain of

atropin, and $\frac{1}{4}$ of a grain of morphin was administered, and the spot to be punctured was anesthetized with ethyl chlorid, while a mustard plaster was applied to the epigastrium. This was the preliminary procedure in all but the first case, in which the amount of the hypodermic injection was decreased to one-half the quantity given in the other cases.

TWO CASES OF MEDULLARY NARCOSIS.

By W. L. RODMAN, M.D.,

of Philadelphia.

Professor of the Principles of Surgery and Clinical Surgery, Medical College, and Professor of the Principles of Surgery in the Woman's Medical College.

As requested, I herewith report only two cases in which I have employed subarachnoid injection as a means of producing anesthesia. I was ready to use it several days before October 2, the date of my first injection, but in handling the syringe which I had had carefully prepared, it accidentally fell from my hand and broke. A delay of several days was necessitated in order that I might obtain a new syringe. My first case was operated on October 2, at 11 A.M.

CASE 1.—I. S., 45 years of age, colored, was born in England, and by occupation was a blacksmith. He presented himself to me with a large swelling at the inner side of the popliteal space of the right limb. An enlargement of the bursa lying beneath the tendon of the semitendinosus muscle was diagnosed. It had caused considerable pain to the patient who complained of it particularly during working hours. He had a mitral murmur and some kidney disease; on this account, and the further objection to giving ether or chloroform in the prone position, I decided to employ the treatment now used many times by Tuffier and others so successfully. He himself preferred that it should be used instead of ether or chloroform. At 11 o'clock precisely, the puncture was made in the fourth lumbar interspace, the needle passing easily into the spinal canal. Its passage was facilitated by having the patient fold his arms and bend forward just before the puncture was made. Then shortly there was an escape of a few drops of cephalo-rachidian fluid unmingled with blood. I was then positive that the needle was in the proper position, and 15 minims of a sterile 2% solution of cocaine were slowly injected. Nearly one minute was consumed in the injection, as Tuffier, Murphy, and others insist upon this precaution. At the time of the injection the pulse was 68, the respiration 24, the temperature 98.6. In four minutes there was some disposition to nausea. In six minutes nausea was marked and the patient became covered with profuse perspiration. Vomiting began a few seconds later, and was quite marked until it was checked very promptly by the administration of pellets of ice. In six minutes after the injection the patient complained of numbness of the feet and tingling in his limbs. There was then partial anesthesia and abolition of the reflexes. In 10 minutes the anesthesia was absolute, and the vomiting having ceased, the patient was placed in a prone position, an incision was made over the tumor and its enucleation begun. As I have said, the anesthesia was complete. He did not even feel the pressure of my knife in going through the skin. The diagnosis of an enlarged bursa was confirmed, and it was removed in 10 minutes. In 20 minutes from the time of incision the wound was closed and dressed. I particularly asked if pain was felt during the introduction of the stitches, and always was answered in the negative. Dr. Robert Brodie, who was present, kindly offered to note the condition of the pulse and respirations during the operation. From the notes furnished by Dr. Brodie I see that the pulse rose to 120. The respirations he did not count, or has failed to make record of them. The patient was a very nervous man and the increase in the pulse was, I think, partly due to that, but more to the accompanying nausea and vomiting. I should have said that the vomited matter was at first mucous, later on bilious in character.

I also see from the notes of Dr. Brodie that while the anesthesia was complete, the patient retained the sense of touch. He could feel that he was being touched by the needle though it gave him no pain whatsoever. The patient said "his legs felt like each had a brick on it."

I myself saw the patient in the ward at 11 45. He was perfectly calm and tranquil; in no pain; the nausea had entirely passed away, the skin was no longer relaxed, his pulse was 60, temperature 98°, respirations 24. At 4 P.M. the pulse was still 60, respirations 32, temperature 99°. The patient passed a wakeful night, but had no return of any unpleasant symptoms. On the morning of October 3 his pulse was 86, respirations 22, temperature 99.4° in the mouth. The evening of the 3d the pulse was 72, respirations 32, temperature 99.2°. The temperature never rose higher than 99.4° at any time after the operation. The pulse was always about 70. The wound healed by first intention under one dressing; the stitches being removed on the tenth day. The man was discharged from the hospital on October 20. The puncture of the lumbar region was at once closed with iodoform collodion, and over this a pad of sterile gauze was placed. There was at no time during his stay in the hospital any pain or uneasiness in the region of the puncture. It would be a work of supererogation to detail how everything of an aseptic and antiseptic nature was done to make the instruments and operative field sterile.

CASE 2.—Although this patient, B—, gives his age as 57, he looks as if he were 10 years older. He has lead a life of dissipation, though latterly he has not been drinking. He has had a very extensive ulcer of the leg for many years. Some time since, an effort was made to give him ether, and he says that he took it so badly, it had to be abandoned, and that he was then advised never to take it again. He also has a weak heart, but, after a very careful examination, there was no positive evidence of organic disease. He had such a fear of ether, that when he was admitted to the ward he at once asked me not to give it to him, and that anesthesia should be produced in some other way. At my clinic, October 24, at 1 o'clock, cocain—15 minims of a 2% solution—was injected into the fourth lumbar interspace. The needle went readily into position, and in 2 seconds there was an escape of cephalo rachidian fluid, drop by drop, so that every one present could see it. It was not even tinged with blood, but of a very pale, limpid appearance. The cocain was slowly injected, about 1 minute being consumed. Professor Anders was asked to be present and to note accurately the condition of the pulse, respirations, and any other points of interest. "I found the first effect was to increase the frequency of the pulse and respirations considerably, and that, while the pulse soon (at the end of 20 minutes) had returned to almost its normal rate, the respirations continued at 36 per minute after the lapse of 34 minutes. Epigastric oppression developed after 10 minutes, and vomiting after 15 minutes. The nausea and vomiting ceased in the course of 10 minutes. While nauseated, the mucous surfaces looked cyanotic, and the skin surface pale and covered with sweat, though the latter symptom was not well marked."

In 10 minutes from the time of the injection I had the patient raise his own leg, hold it in position, and I at once made a circular sweep with an amputating knife at the junction of the upper and middle thirds of the leg. He did not feel this, or any other step of a regular Schede operation. On the contrary, he moved his leg up and down, from side to side, just as I requested. After this the extensive ulcer was curetted; both wounds were dressed, and after the dressings had been completed the patient asked me if I was ready to begin the operation. I may say he was blindfolded up to this time. He was much surprised to find the operation over and the stretcher ready to take him to the ward. After my clinic was over I went into the ward and found this patient congratulating himself that he was feeling so much better than the one just opposite him, who had taken ether. There was not the slightest nausea, his pulse was 96 and regular, his countenance was placid, and he expressed himself as "feeling better and freer from pain than he had done for 12 years." I was impressed, as I am sure all must have been who saw the demonstration, with the advantage of operating upon an extremity by this method. It is of great assistance to have the cooperation of a patient during the steps of an operation. I believe that a part of the perfect success attending this injection was due to the fact that I

kept the patient blindfolded. No one, I take it, can look at his own blood without misgivings and apprehensions. There was a minimum amount of nausea, nothing like the amount experienced by the first patient. At 7 P.M. his pulse was 88, temperature 98.2°, respirations 24. If all the patients behaved as well under this method of anesthesia as this one, I should be disposed to use it more frequently than I have hitherto thought probable. The cocain used in this case, like that in Case 1, was sterilized by heating it to 80° C., 4 or 5 times, and then sealing it up in glass ampullae. This, I believe, insures sterility. Eucain may be boiled, and ideally might be preferred, yet in several instances reported, it has failed to produce anesthesia.

COCAIN ANESTHESIA OF THE SPINAL CORD.

By ERNEST LAPLACE, M.D.,

of Philadelphia.

Professor of Surgery in the Medico-Chirurgical College.

CASE 1.—M. T., aged 72, was admitted to the Medico-Chirurgical Hospital, October 10, with a large sloughing varicose ulcer of the right leg. A weak heart and albumin in the urine led to the use of cocain anesthesia of the cord to scrape the ulcer and denude the edges. On October 12 the patient had fasted since yesterday, the pulse 82, temperature 98.3. At 11.32 A.M., 2 cc. of 2% solution of sterilized cocain hydrochlorate was injected between the fourth and fifth lumbar vertebrae into the subarachnoid space. At 11.40 A.M. the pulse was 110 and patient grew pale and restless. At 11.43 the patient became cyanotic and had nausea; the pulse was 120. There was a spasm of the muscles of respiration. I administered nitroglycerin $\frac{1}{10}$ grain hypodermically. There was involuntary passage of feces; anesthesia existed from the feet to the knee. At 11.45 the patient breathed more easily, the pallor disappeared, the pulse was 100; anesthesia extended to the nipples. At 11.50 the operation of scraping the leg ulcer 3 inches in diameter, almost to the tibia, was done with a sharp curet. The ulcer was pared of its edges about $\frac{1}{4}$ inch around. Anesthesia was perfect. Patient sighed frequently. At 12.30 anesthesia persisted up to the diaphragm, the pulse was 64, temperature 97.5, respiration 22. At 12.45 sensation was restored from the diaphragm to the ileocecal line. At 1 P.M. sensation was restored to the knees. At 1.05 P.M. sensation was entirely restored to the extremities. The patient was given some ice, as he felt nauseated and thirsty. Since then he has shown no symptoms of interest. There was little or no headache following in this case.

The symptoms of dyspnea came on with remarkable suddenness. I used 2 cc. of the 2% solution, which was perhaps a large dose for a man of 72 years. The dyspnea was, however, immediately remedied by the hypodermic injection of $\frac{1}{10}$ of a grain of nitroglycerin; 2 cc. of a 2% cocain solution is the dose now used generally by Tuffier, in whose clinic I watched a large number of cases this summer without a single accident.

Summary.—The patient was a male, 72 years of age. The injection was 2 cc. of a 2% solution; toxic symptoms began in 10 minutes; anesthesia of the extremities followed in 11 minutes; anesthesia extended to the nipples in 13 minutes; anesthesia began to disappear about the abdomen in 73 minutes with total disappearance in the extremities in 83 minutes from the moment of injection. The total duration of anesthesia from the nipples to the pubis was from 60 to 65 minutes. The total duration of anesthesia from the pubis to the toes was from 65 to 72 minutes.

In future cases, I intend to give a preliminary injection of $\frac{1}{10}$ gr. of nitroglycerin, to counteract the depressing effect of the cocain.

CASE 2.—As an anomaly that may be met with in the attempt to practise the cocain anesthesia of the cord, the following case is deemed worthy of being recorded:—M. H., aged 42 years, suffered with cholelithiasis. There was a history of syphilis. The operation was cholecystostomy. On October 6, cocain anesthesia was attempted by injection into the spine. The fifth lumbar interspace was selected, according to Tuffier's directions. The needle used was the same as that used by

Tuffier in his numerous cases, and which I brought from Paris with me and was used on the previous case reported here. No difficulty was found in introducing the needle in the proper place, but no cerebrospinal fluid exuded. It was introduced several times in this space, then in the fourth, then in the third, without allowing cerebrospinal fluid to exude. All care was taken to exhaust the air with the syringe after the plan used by Tuffier, and to ensure that the needle was not plugged, but to no avail. Thus 12 punctures were made; the needle surely reached the cord and touched it, for after the point fell on the vertebra on one side, and by moving slightly it penetrated the intervertebral space, it was pushed deeper and deeper and on reaching the cord, gave, as the patient expressed it, "a terrible electric shock" to her extremities. Nothing but blood would be drawn into the syringe when the needle was gradually withdrawn after suction had been made. It was then judged improper to inject cocain solution,—for the absence of cerebrospinal fluid would have limited the action of the cocain locally instead of anesthetizing the course of the spinal cord. Possibly there was an obliteration of the sac in that region due to chronic syphilitic infection. The patient was subsequently operated upon under ether.

SUBARACHNOID INJECTIONS OF COCAIN AS A SUBSTITUTE FOR GENERAL ANESTHESIA.

By A. M. PHELPS, M.D., A.M.,
of New York.

President of the New York State Medical Society; President of the American Orthopedic Association for 1894; Member of the New York Academy of Medicine and the New York County Medical Society; Visiting Surgeon to the New York City Hospital; Professor of Orthopedic Surgery and Visiting Orthopedic Surgeon to the New York Post-Graduate School and Hospital; Professor of Surgery to the Medical Department of the University of Vermont from 1889 to 1899.

It is not my purpose to enter into a long discussion of the history of cocain anesthesia, particularly of the spinal cord. Its history has been carefully compiled by Dr. John B. Murphy, of Chicago, and published in the *Chicago Clinic*, and by others equally as eminent.

Undoubtedly, Corning is the original discoverer of this peculiar method of cocain anesthesia. Bier published the method of Corning in the German journals years after the last paper of Corning was published in the *New York Medical Record*. The description of the method by Bier so closely resembles that of Corning, that one is inclined to believe that Bier may have received his inspiration from Corning's articles. Corning, in the *New York Medical Journal* for October 31, 1885, published the result of his work, and demonstrated that anesthesia could be produced in this way, and suggested the treatment in the *New York Medical Record* of March 17, 1888, page 291, "Painful diseases of the spinal cord could be treated in this manner."

Professor Tuffier is probably the one man in the whole world who has done more to introduce this method of spinal anesthesia than any other. In Murphy's excellent article he parallels the writing of Tuffier with that of Corning, and any one who reads these parallels must become thoroughly satisfied that Tuffier received his inspiration from Corning, even to the invention of the needle. All that he says had been said years before, and was well known to the profession of America. I quote these parallels from Dr. Murphy's article to show the profession how unconscious cerebration may be responsible for very great injustices:

CORNING SAYS:

The ordinary needles with very oblique bevel possess one disadvantage. This disadvantage is that the orifice

TUFFIER SAYS:

The needle must be sufficiently long to penetrate easily the space between the skin and the subarachnoid

of the needle may only be partially in the subarachnoid space, while the other portion of the needle may be without the sheath, so that the injection may flow partially into the subarachnoid space and partly into the surrounding tissues, so that this needle with a short bevel is what he prefers.

In a few of my trials I failed to obtain a complete and perfect analgesia. This failure was due to the fact that I employed an old solution of cocain. The solution was not absolutely limpid. In these cases, by following the unsuccessful injection with a fresh solution the desired result was obtained.

In my first case, to make the injection, I used to place the patient in the left lateral position, the thighs flexed on the abdomen and the body bent forward. It has seemed to me that in this position the spinal column is subject to deviations, is subject to flexures, which make lumbar puncture difficult.

The patient being warned, when the needle penetrates the tissues, he does not jerk, and by not jerking he does not deviate the needle from its proper course.

When the same posture is used the needle must be inserted perpendicularly, from backward forward.

If this dose be exceeded, epigastric anxiety is more marked, vomiting is more frequent, but, nevertheless, even with a large dose, I have never observed any alarming symptoms.

It was my good fortune to be in Germany during the years 1882, 1883, and 1884, during the time of the first cocain craze. The profession was running riot. All manner of devices for its application were being presented to societies, and in the various scientific bodies that I happened to attend I heard from the lips of the most eminent surgeons advice in regard to the use of cocain, which, if it had been followed, must necessarily have resulted in a very large percentage of mortality. For instance, one made the statement that a 10% solution of cocain was a perfectly safe one to use with a hypodermic needle under all circumstances, and that even stronger solutions could be used; that these solutions in dentistry rendered the parts anesthetic, and that he thought the hypodermic use of them should be urged upon the profession.

That week there was a death in the dentist's chair from the injection of a 10% solution of cocain into the

space. This interval varies in length, according to the muscular development and obesity of the patient. The needle must be of platinum. It must be easily sterilized and be 9 cm long. . . . It must be solid, so as not to bend when it comes in contact with the vertebral column. Its end must have a short bevel.

I employ a 2% solution of cocain. This solution must be sterile and recent; old solutions must be discarded. This is important.

The patient is in the sitting posture, both arms carried forward. The field of injection is thoroughly ascertained. Locate the iliac crests. An imaginary line connecting these two crests passes through the fourth lumbar vertebra. By injecting beneath the line you penetrate the medullary canal. As soon as you have located with the left index finger this spinous process, tell the patient to bend forward so as to make a big bag.

Then it is always wise to tell the patient, "I am going to stick you with a needle; you will feel some pain, but do not move."

I insert the needle to the right of the vertebral column, about 1 cm. from the line of the spinous process.

The injection is made slowly; it should be completed in one minute. The dose injected should not exceed 15 mgm. of cocain.

gums of a patient. A warning note was given to the profession soon after, and such strong solutions were rapidly abandoned.

I returned to this country in 1884, and found that cocain anesthesia was running the same riot that it had already run in Germany, and in other countries of Europe. That winter, in the New York State Society, a prominent member advocated the use of strong solutions of cocain in surgical practice, and mentioned in particular its application to dental surgery. Others were writing on the subject. Our journals were filled with advice in regard to this particular method and its administration. I remember well that Corning's work appeared a little later, and but few as yet had raised a voice against the dangers of cocain anesthesia by hypodermic injections.

Within twelve months from that time I witnessed the death of two patients from cocain anesthesia. One occurred later in my own practice, and I had only used in that case a 2% solution of cocain hypodermically, 30 minims, and the patient died within two hours of the administration. The other two cases to which I refer occurred in the practice of dentists who had injected a 10% solution into the gums.

The object of injecting the stronger solutions, it was urged, was for the purpose of producing prolonged and profound anesthesia. I found that a 0.5 of 1% solution of cocain, when injected hypodermically into the extremity or in the abdominal parietes, produced a prolonged and profound anesthesia, and amputations, and even extensive laparotomies for obstruction of the intestine I have repeatedly performed with these weak solutions used as already stated, where general anesthesia was impossible. In 1886 I did an extensive laparotomy for Dr. Brewer, of Madrid, St. Lawrence County, N. Y., now of Utica, using a 0.25 of 1% solution of cocain, injecting a large quantity of the fluid in the abdominal parietes. The operation was performed without pain. And then again I have seen the most alarming symptoms arise from the injection of even this weak solution in large quantities, say two drams. Since the death of the patient to which I allude, I have been very careful about using any solution stronger than 1% and only a very few minims of that. Now it is urged upon the profession that they inject into the spinal canal a 4% solution of cocain. Bier uses 2%. Others have injected as strong as 8% or 10%, and we are asked to substitute this method of anesthesia, for operations below the diaphragm, for the anesthesia of ether or chloroform. There is one death in 75,000 administrations of ether, and one in 11,000 administrations of chloroform. If it can be shown to the profession that this form of local cocain anesthesia can be administered more than 75,000 times without death, then we would be justified in abandoning the general anesthesia of ether for that of cocain. Until this is proved, I admonish the profession to advance with great caution. In my whole life I have seen only one death from ether anesthesia, and one from chloroform. Within two years, I saw three deaths from cocain administered hypodermically. I place this upon record, and I believe that it corresponds closely, if not exactly, with that of the observations of many surgeons of wide experience. Tuffier reports 5 deaths in 125 injections into the spinal canal. One of the cases died almost immediately after the injection. I can understand and appreciate the great value of the discovery of Corning. I can understand that in a

certain class of cases in which chloroform or ether anesthesia would result in death on account of organic disease of heart, lungs or kidneys, or some other peculiarity of the patient, this form of anesthesia would be proper and justifiable, but until it is proved that the mortality is less than one in 75,000, the profession should not accept it as a substitute for general anesthesia in any operation. I am of the opinion that if a 4% solution, or even a 2% solution, is injected in the spinal canal of 1,000 individuals taken indiscriminately, that the mortality will be greater than 1%. Every surgeon has patients upon whom he has operated under local cocain anesthesia administered hypodermically, and he knows that there is an idiosyncrasy in some of those patients against cocain, and if profound anesthesia was produced by the injection of a dose of cocain to one individual which would be a small dose in another individual, death would certainly be the result in certain cases if a full dose were given.

Then, in conclusion, let us hasten slowly. Let these experiments be done by men of mature judgment, of long experience, of clear heads. And so long as the profession has an anesthetic in ether that has so low a rate of mortality, or in nitrous-oxid gas in which the mortality is almost nothing, they will be loath to substitute for it a method of anesthesia which must necessarily have a great mortality.

I was fortunate enough to listen to the discussions upon this subject while in Paris last summer, and I must say that I was very favorably impressed with what I saw until I learned that two deaths had already occurred there during the summer from this method of administration of cocain. And now that we are occasionally hearing the mutterings of dissent in the profession on this side of the water, and hearing of a death or extremely alarming symptoms, let the profession take warning.

A NOTE ON THE USE OF NITROUS OXID AND ETHER AS AN ANESTHETIC.

By THOS. R. BROWN, M.D., AND HOWARD
A. KELLY, M.D.,

of Baltimore, Md.

THE choice of an anesthetic is of such paramount importance, not only to the patient who is operated on, but also to the surgeon who performs the operation, that anything which promises to render anesthetization easier for the patient, either by shortening the period of time required to render him or her unconscious, or to lessen the unpleasant symptoms preceding or following anesthesia, should be given careful consideration by all who constantly make use of anesthetics.

Most anesthetizers have agreed that while chloroform is the more pleasant, ether is much the more safe anesthetic. On the other hand, the irritation of the throat during the long period of time required for complete anesthesia by this latter chemical, as well as the almost invariable and often protracted nausea following its use, render it, although the more safe, much the more unpleasant anesthetic of the two. In recent years, other anesthetics or mixtures of anesthetics have been used, but the only method which has gained a wide enough vogue to be seriously considered is the combination of nitrous-oxid gas either with ether or with chloroform, preferably, of course, with the former, due to its greater safety. Stimulated by the favorable reports of the

method in the hands of numerous of the London and New York anesthetizers, and feeling sure from a personal study of the method as given by Dr. Goldan and several other of our New York confrères, who most courteously demonstrated it to us in a number of cases both in private houses and in hospital, we have, for the past eight months, been using the combined nitrous oxid and ether method in practically all the cases operated upon at Dr. Kelly's private hospital. These cases number between 200 and 300, and comprise all varieties of abdominal, perineal, vesical, renal, ureteral, and rectal operations.

The instrument used was that devised by Dr. Bennett, of New York, and made by Tiemann. This instrument in our hands has proved absolutely satisfactory, and too much credit cannot be given to Dr. Bennett for so successfully solving the problem of controlling definitely the supplies of nitrous-oxid gas, ether vapor, and air. Dr. Goldan's instrument also promises to be extremely satisfactory.

The advantages of the method have been so distinct to the patient, the surgeon, and the anesthetizer, that we feel that the use of the older methods, that is, the administration of ether alone or of chloroform alone, or of the A. C. E. mixture, should give place to this newer and more effective mode. To the patient, these advantages are: The rapidity with which he or she becomes anesthetized, the freedom from all unpleasant symptoms during the process of anesthetization, and the distinct diminution in the after-symptoms, especially as regards nausea; to the surgeon the great advantage is the shortening of time; to the anesthetizer the advantages are obviously a combination of the two preceding. To these advantages must be added the much diminished quantity of ether employed and the much shorter time required by the patient to recover entirely from the effects of the anesthetic.

The possible disadvantages of the method are the cyanosis during the administration of the nitrous oxid, the increased secretion of mucus, and any untoward postoperative effects which may be shown to be directly referable to the use of the nitrous oxid.

As to the cyanosis, while in a certain proportion of cases a slight degree of cyanosis seems inevitable, yet without doubt this largely depends upon the skill of the anesthetizer and his experience, so that we have found that the presence or the degree of cyanosis is distinctly diminishing with our constantly increasing experience with the method; in many cases it is wanting altogether, in others it is present in only a very slight degree, while in a very few,—and these last are constantly diminishing in number,—is the cyanosis marked. Of course, only constant experience in the mixing of the nitrous oxid and the air will bring about the ideal anesthetization, but we feel sure that many of the symptoms of asphyxia may be eliminated in the hands of those who are constantly using the method.

As to the secretion of mucus, while this seemed to be increased when we first made use of the method in a certain number of cases, now with our increasing experience this secretion is constantly decreasing, so that it is now certainly no more and, we think, distinctly less than after the use of ether alone.

As regards postoperative symptoms, the nausea is undoubtedly markedly lessened, in some cases absent altogether; in a certain very small proportion of cases, a slight headache is found, while in two of our cases, both very hysterical young women, and in each of whom

nephropexy was performed, quite marked mental symptoms were present for several days. We mention these cases, not because we regard them as being probably due to the method, but simply to make the record more complete.

Perhaps it will be of interest to give in detail a few of the salient points in the use of this method in the last 25 or 30 cases in which it has been used by us.

To render this easier of reference it will perhaps be better to tabulate the results.

In this table the time was taken by half minutes, and for that reason errors of less than 15 seconds may have occurred, while for the same reason slight errors may have been present in the quantity of ether used, as this was estimated by quarter cans (25 grams). This was done simply to facilitate matters, although if we had known that the result would subsequently be published even these slight errors would have been eradicated. They are, however, so slight as to make no real difference in the value of the table.

It will be seen, from a consideration of the table, that loss of consciousness from the use of the nitrous-oxid gas was produced in from 1 to 2½ minutes, and complete anesthesia in from 2 to 5 minutes. The cases, however, were all women and therefore easier to anesthetize than the average of general hospital patients.

D. and C.	78	78	2	3	15	1 "	100
Hyst. my.	104	92	1	2½	1 25	1 "	200

In all of these cases, except the nephropexy, the nausea after operation was slight, and in some cases practically absent altogether.

The Bennett instrument was employed only to induce complete anesthesia, after which an ordinary cone was

used during the rest of the procedure; this was done because of the heaviness and rather unwieldy character of the Bennett instrument, and therefore to prevent the anesthetist's hands from becoming weary.

In our experience the method has seemed to possess so many advantages to the patient, operator, and anesthetist, and so few disadvantages to any of these, that it has become an indispensable part of our operative technic; and that it has proved satisfactory can be easily judged from the fact that after over 200 anesthetizations with the method, our faith in it, instead of diminishing with experience, has increased a hundred-fold.

ETHYL BROMID IN OBSTETRICS AND GYNECOLOGY.

By WILMER KRUSEN, M.D.,

of Philadelphia.

Instructor in Gynecology, Jefferson Medical College; Assistant Gynecologist, St. Joseph's Hospital.

ETHYL BROMID was first proposed as an anesthetic by Dr. Thomas Nunnally in 1846, but was not brought earnestly before the profession until 1875-77, when attention was called to it by Rabuteau in France, and Laurence Turnbull in the United States. In 1879, Turnbull reported the results observed in his first 21 cases; and in 1885, E. E. Montgomery, in a contribution to the *American Journal of Obstetrics*, recommended it as a valuable anesthetic in labor. This, and Montgomery's later contributions to literature have probably done more than those of any other American writer, to promote the employment of this anesthetic in obstetrics and gynecology. A brief description of this drug is important. Ethyl bromid (monobromethane), C_2H_5Br , occurs as a clear, colorless, or almost colorless, volatile, not readily inflammable liquid, of an agreeable odor. Its specific gravity is 1.45 to 1.50; boiling point, between 36° and 40° C. It must not be confounded with ethylene bromid (dibrom-ethane), a substance possessing very dangerous properties. It is very important that a chemically pure article should be procured, better in the original hermetically sealed tubes which contain one ounce avoirdupois. It should always be kept in a cool, dark place, since it is exceedingly prone to decompose under the conjoint action of air and light. A brownish, poorly volatile article is not fit for use.

As an anesthetic to be used in cases in which a brief period of anesthesia is desired, ethyl bromid is the ideal drug. For the past seven years I have used it extensively in obstetric and gynecologic practice and I have yet to witness the first accident or alarming symptom. As in the use of all anesthetics, great caution must be exercised. A careful study of those instances in which accidents have occurred shows that, although the drug is not devoid of danger, there is no sufficient reason for believing, that with an absolutely pure article, the danger is any greater than with chloroform and very little greater than with ether. In obstetrics its use is indicated when an agent is desired to relieve the severity of labor-pains; but it is not indicated when prolonged manipulations, such as version or high application of forceps, etc., are required. The ideal obstetric anesthetic is one which acts rapidly, surely and safely, with effect of short duration, and which can be carried in a small compass. Ethyl bromid fulfils these requirements. A characteristic that has been many times noted is the tendency for sensibility to pain to be lost before consciousness is entirely destroyed, thus enabling

the patient to cooperate with the obstetrician without intense suffering. If properly administered it does not arrest the pains, produce complete unconsciousness, or cause uterine inertia or relaxation.

The method of using it in obstetric practice is as follows: During the latter part of the second stage of labor, as the suffering becomes severe, the drug is administered with the advent of each pain, by holding over the face of the patient a napkin on which a few drops have been poured. This is removed as the pain subsides. There is no choking or suffocation and an entire absence of any stage of excitement. After one inhalation the patient usually begs for the drug with the advent of each recurring pain. As small quantities are administered the sensation of pain will be blunted while intelligence is retained, and the patient will be perfectly subject to control and ready to render or withhold voluntary efforts as desired. Any obstetrician that once gives this anesthetic a fair trial will find that it affords great satisfaction and relief to his patient and increases materially her belief in his humanity and desire to mitigate all unnecessary suffering.

In gynecologic practice it has long been recognized that in order to make a thorough bimanual examination on nervous patients with rigid or tender abdominal walls, an anesthetic must be used. To administer ether or chloroform for this purpose means a considerable expenditure of time, and often exceedingly unpleasant sequels. They cannot be used in the physician's office with any hope of getting rid of the patient in a reasonable length of time. Nitrous oxid, although rapid in action, requires too expensive and complicated an outfit to make it a satisfactory agent, while ethyl bromid, being exceedingly evanescent in action and rarely productive of vomiting and other sequels, seems to be peculiarly useful and well adapted for this purpose.

This drug has also been advantageously employed in the treatment of the following conditions: Dilation of the urethra or anus; evacuation of vulvovaginal abscesses; for vaginal section when there is an accumulation of pus, blood or exudate in the pelvis; abscess or sinuses of the anterior abdominal wall; incision of mammary abscesses, and many of the minor gynecologic operations which can be quickly performed. The method of administering it for this class of cases is to pour one dram of the drug on a cone-shaped towel or napkin which is applied over the mouth and nose with the edges held snugly to the face so that no air may enter. Narcosis usually comes on in from 30 to 40 seconds and lasts from 2 to 3 minutes; when unconsciousness is complete the mask should be removed, and it is rarely necessary for it to be reapplied. Although if care is exercised a second quantity may be administered, yet it is better, if more prolonged unconsciousness is desired, to continue the narcosis thus induced with chloroform or ether. In fact, in excitable or insane patients, I have found that ethyl bromid will materially shorten the excitement of the initial stage and render the use of the other agents much less difficult.

As in the administration of all anesthetics, a thorough examination of the patient should be made. Dangerous lesions of the heart, kidneys, or lungs are strong contraindications. There are certain patients, especially alcoholics, who greatly resist this drug, and under no circumstances should the attempt to force the anesthesia be made.

The employment of a pure drug must be insisted upon. This is emphasized by the statement of Gilles, who claims that there is no fatal result on record in which it has been proved that a chemically pure bromid has been administered. This writer also states that there were given in Germany 20,000 administrations without a single fatal result. The narcosis is only in rare instances accompanied by general muscular relaxation; indeed, frequently the general muscular tonus is increased; but even during the state of muscular rigidity analgesia is perfect and the surgeon may proceed with the operation without the patient experiencing pain. The pupillary and corneal reflexes are usually preserved and the eyes are sometimes wide open and crossed from muscular contraction. The pulse and respiration should be vigilantly watched and the drug withdrawn if danger threatens.

The advantages which may be confidently claimed for this agent are: 1. The short space of time required to render the patient unconscious. 2. The small quantity of the drug employed and the rapidity of its elimination from the system. 3. The simplicity of its administration, no cumbersome apparatus or inhaler being required. 4. The comparative freedom from unpleasant sequels, such as headache, nausea, vomiting, etc., which characterize the other more popular anesthetics.

Gangrene Complicating Typhoid Fever.—P. W. Howle (*Virginia Medical Semimonthly*, Vol. IV, p. 611). A boy of 19 was taken with typhoid fever which was of usual severity for the first 2 weeks. At the end of the second week he developed pneumonia of the lower lobe of the right lung. On the eighteenth day his heart began to weaken and on the twenty-fourth day he developed a state of almost collapse with tympanites and severe abdominal pain. The abdominal distention subsided by the use of turpentine stupes and he began to improve. The fever had been treated by frequent cold baths. On the twenty-seventh day he complained of pain in his feet, which continued to increase. Purple spots appeared and by the thirty-fifth day both feet were gangrenous as high as the ankles. Symptoms of sepsis developed and death resulted the following day. [M. B. T.]

The Relation of the Specific Gravity of the Blood to Its Percentage of Hemoglobin.—Busch, Kerr, and Filsinger (*Buffalo Medical Journal*, October, 1900) have tested the specific gravity of the blood by Hammerschlag's method of floating a drop of blood in a mixture of benzol and chloroform in 80 cases. Thirty-one of the patients were in a state of health, 17 were suffering from simple anemia, and 8 from pernicious anemia; the remainder from various other diseases. Blood-counts were also made and the results compared with the estimations by the Fleischl and the Gowers' methods. They conclude that in most cases the specific gravity and the percentage of hemoglobin of the blood present such a close resemblance to one another that the latter may be predicted from the former with sufficient accuracy for clinical purposes. They believe that both Fleischl's and Gowers' instruments are liable to an error of 10% or more. There is liable to be very slight if any error in the determination of the specific gravity by Hammerschlag's method. [M. B. T.]

Thyroid Extract in Obesity, Scleroderma Psoriasis and Fibromyoma of the Uterus.—Weber (*New York Postgraduate*, September, 1900) says that he has made extensive trial of thyroid extract in cases of obesity. Loss of weight and fat was quite noticeable, but lasted no longer than the exhibition of the remedy; patients gained rapidly and returned to their former weight soon after its discontinuance. In one case of scleroderma in which the stiffness of the skin involved the arm, parts of the shoulder and breast, recovery followed after the patient had taken some 500 or 600 5-grain tablets to the exclusion of all other medicines and without any unpleasant by-effects. The thyroid extract

was given in a case of well-defined fibromyoma of the uterus and this treatment was followed by gradual diminution of the tumor until at the expiration of 4 months the fibromyoma was reported reduced to a minimum and practically cured. In a fourth case, psoriasis which had existed for about 10 years, the extract, in doses of 5 grains 3 times daily during a period of 2 months, resulted in a permanent cure. The local remedy used was a 25% aristol salve. [G. C. H.]

Rheumatic Diseases of the Ear.—Uchermann (*Transactions International Otological Congress*, August, 1899) sums up this condition as follows: 1. Rheumatic fever is sometimes preceded and sometimes accompanied by otalgia, alone or together with an acute swelling and infection of the drum and adjacent bony meatus, followed by a serous or a serofibrinous excretion in the middle ear; or it may be complicated during its progress with affections of the middle ear and the internal ear. 2. There are other more independent rheumatic ear diseases in persons of a rheumatic constitution or tendency. The ear affection appears as an otitis media "serosa" with yellowish half fibrinous exudations, or as a sclerosis of progressive character. 3. The characteristics of the different forms are: in the acute forms, painfulness, excessive injections, and the tendency to the formation of infiltrations and exudations; in the chronic forms, the tendency to the formation of fibrinous exudations and the tendency to affect the bony capsule, with strong tinnitus, and slow progression. Salicylic acid seems to influence the acute forms but not the chronic forms, the latter being influenced more by general rheumatic treatment. [A. B. C.]

Periosteal Tendon-Grafting.—Lange (*Zeitsch. f. Orth. Chir.*, 8 Band, p. 30) reports 2 cases in which one or more muscles of the lower leg had become paralyzed as the result of poliomyelitis, which were benefited by transplanting tendons of sound muscles. In the first case the extensor communis digitorum and the peronei muscles were affected so that during the course of a few years marked clubfoot had developed. At the operation the deformity was corrected and the tibialis anticus tendon split from its insertion on the internal cuneiform up to the beginning of its muscular portion. The external half of the tendon was detached from its insertion and pushed under the skin of the back of the foot and the end sutured to the periosteum of the cuboid bone. The result in this case after 10 months was most satisfactory, the patient being able to walk with his foot in the proper position, half way between pronation and supination. In the second case the gastrocnemius was the muscle affected and the remedy was found in the peroneus longus, whose tendon was fastened to the periosteum on the median side of the os calcis. Two and one-half years after the result was still excellent, the patient being able to flex and extend his foot at will. [G. B. W.]

Coxa Vara.—Shanz (*Zeitschrift f. Chirurgie*, Band 8, p. 180) speaks of the recognition of coxa vara in its earlier stages. He says that objective symptoms will be found only when the condition has progressed beyond the incipient stage, and deformity has already developed. About the earliest of the objective symptoms are adduction and outward rotation, though the latter does not appear in all cases. When present, subjective symptoms give far better hold for the making of an early diagnosis, but just as in scoliosis and flatfoot there are numbers of patients who will have well-marked deformities without any apparent discomfort, so here the subjective symptoms are often lacking. When the subjective symptoms do appear, the first that will be noticed is a discomfort, which develops by walking or standing, but which rapidly disappears on lying down. This discomfort at first is simply a sense of tire, but later develops into unbearable pain. In many cases, pressure over the hip will elicit tenderness and occasionally considerable muscular fixation of the joint will be noticed. When the sense of tire has passed over into pain, the patient will begin to limp, and the degree of limping corresponds to the amount of pain and also to the amount of deformity which may be present. From these symptoms it will be seen that in the early stages of coxa vara it is most difficult to differentiate this disease from tuberculous coxitis, and the only sign which is at all distinguishing is the bilateral character, which is almost always present in coxa vara, and is seldom present in the tuberculous diseases of the hip. [G. B. W.]

Rabies in the District of Columbia.—Dr. D. E. Salmon, Chief of the Bureau of Animal Industry, has performed a public service by issuing a pamphlet in which he subjects to trenchant criticism the course pursued by a Washington newspaper in reference to the recent prevalence of hydrophobia in that city. This newspaper has made itself the mouthpiece of those mischievous agitators who periodically seek to mislead the public on this important subject. They deal, of course, in nothing but the old stock arguments against the reality of this disease, and they absurdly seek to champion the cause of the much-abused dog who offends against public safety by occasionally contracting rabies. These people are harassed by the thought that the dog is controled in the city of Washington by certain salutary laws, and in order to defend his so-called rights they ignore the cardinal principles of common hygiene and common sense. It can hardly be expected of us here to rehash all their stale arguments, but we take time and space to applaud Dr. Salmon's energy in seeking for some of the individuals who not long ago were offering a prize in money for any person who would produce a case of real hydrophobia in a dog. As Dr. Salmon has the facilities occasionally in his laboratory to gratify their demands, and offers to devote the prize-money to philanthropic purposes, it is to be hoped that these benevolent skeptics will now produce their money. It is too much to expect sensational newspapers not to take the wrong side of any question whatever, and we are not surprised that this Washington journal declined to publish Dr. Salmon's very able article.

High Mortality in Puerto Rico.—As the United States has only recently acquired Puerto Rico, the health reports from that island have special interest for American physicians. Dr. W. W. King, of the U. S. Marine-Hospital Service, has just submitted a report on the high mortality at Ponce, and throws much light on the hygienic state of the island. The lower classes of Ponce are a mixture of Spanish, Indian, and negro blood, the latter predominant. Generations of under-feeding, ignorance, and immorality, amidst unsanitary conditions, have produced a race short-statured, flat-chested, and physically weak. These people are shiftless, improvident, and doless, and become, in the face of disease or misfortune, passive and apathetic. The city of Ponce is unhygienic. It is situated on a low-

lying plain, with inadequate surface drainage, and its population is supplied with water from a river that is polluted from numerous sources. The soil is a loose, porous gravel, and is, of course, thoroughly infected.

Among the immediate causes of the recent high mortality was the hurricane. The banana and plantain crops, the mainstay of the people, were almost entirely destroyed. The people ate whatever they could get, and this consisted largely in sugar cane, unripe fruit, and decayed fish, and this unwholesome food was rendered worse by bad cooking.

Dr. King submits a mortality-table which shows that the fatal diseases may be grouped largely under three main headings: anemia, dysentery, and digestive disorders. The unwholesome diet is evidently largely responsible for the disorders of digestion, and these disorders are not specially interesting. Malaria seems, however, to be an occasional cause.

The most important subject in Dr. King's paper is the role played by *Ankylostomum duodenale*. Cases of a pernicious type of anemia seem to be common in Puerto Rico, and the evidence goes to support the belief that they are largely due to this parasite. Malaria may also be a causative factor, but Dr. King thinks it is not universally so, because malaria prevails most along the coast, while this pernicious anemia prevails extensively in the high interior. A wide difference of opinion exists as to the relative part played by the ankylostomum and simple starvation. Both occur frequently in the same patient, and the microscope is not often used to detect the ova of the parasite. The anemia is extreme, but Dr. King does not report the results of any blood-examinations. This is to be regretted. The mucous membranes become colorless, and a marked edema occurs. The cases thus present some resemblance to beriberi, but Dr. King thinks that true beriberi has never yet been observed in Puerto Rico. The cases can hardly be called truly pernicious, because a generous diet often effects a cure; exceptions occur in cases infested with the ankylostomum. Tetanus is also unusually prevalent in the island. Dr. King's paper may serve to remind us that in Puerto Rico we have acquired an interesting field for scientific research.

Careful Scrutiny of Death-Certificates an Element of Accuracy in Statistics.—We have several times insisted on the value of common sense in the

interpretation of statistics. An added factor of great import in the collection of statistics is the necessity for accuracy of information as to the cause and circumstances of death. In the matter of deaths by violence, many physicians and coroners are in the habit of giving the cause of death as "accident," without specifying whether it was a fall from a window, a railway crush, or a runaway; in some instances the lapse of time after the accident has not been taken into account and a surgical operation, such as amputation or exploratory celiotomy, is not mentioned. So, where death has resulted from the action of a poison, the agent employed is often not stated, nor is there information as to whether it was taken accidentally or purposely or administered with homicidal intent. Suicide is often given as the cause of death, without any specification of the means employed. The necessity for careful scrutiny and perhaps subsequent inquiry by the health-officer is often even greater in reference to death from certain diseases. Old age is perhaps the most abused term as a cause of death; many a man or woman of sixty is said to have died of old age, when in reality the cause of death was an enlarged prostate, a cerebral hemorrhage, or a cancer of the gastrointestinal tract. To the nonprofessional health-officer or clerk the incongruity of a death from "old age" at sixty would hardly suggest itself; the thoughtless physician is also apt to overlook the unlikeliness of such an occurrence, but if trained to careful thought and investigation in sanitary matters he will at once feel the necessity for further inquiry when such a certificate is brought to his attention. Some years ago it was not uncommon to see "heart-failure" given as a cause of death; the indefiniteness of this term was often used by sorrowing friends and obliging physicians for the purpose of securing transportation of corpses that had died of diphtheria, scarlet fever, or even smallpox; in addition it was extended by inaccurate observers to cover many other acute or chronic diseases. There are few health-officers that are today willing to accept a certificate of death from "heart-failure" without some further explanation. Anemia, marasmus, exhaustion, debility, and kindred terms too often serve to conceal cancer, or gastroenteritis, or tuberculosis, just as "inflammation of the bowels" or "obstruction" in times past obscured—with perfect honesty and ignorance it is true—deaths from appendicitis, salpingitis, and ruptured ectopic pregnancies. Even a careful and painstaking sanitarian will often make mistakes in accepting causes of death that are incorrectly given or inadequately expressed. How much greater is the chance of error when uneducated persons act as health-officers or as clerks in charge of vital statistics! Too much care cannot be exercised in connection with every record of a death and every practitioner can contribute his small mite to better existing conditions, make public records more accurate, and enhance the value of mortuary statistics.

An Experimental Study in Oxaluria.—Dr. Helen Baldwin, in the *Journal of Experimental Medicine*, No. 1, 1900, has contributed a paper on this interesting subject. After the discovery of calcium oxalate crystals in the urine by Donné, in 1838, there resulted a description of a so called oxalic-acid diathesis, which was thought by certain clinicians, notably Prout, Golding-Bird, and Begbie, to be of much importance. This view has been quite largely adopted, although Smoler, Neubauer and others showed that calcium oxalate was present in solution in the urine of a large percentage of persons, but that the salt was not always precipitated. This led Dunlop to the view that all the oxalic acid excreted in the urine had been ingested with the food, and that it was never formed in the animal organism by metabolism.

Dr. Baldwin has sought to test the accuracy of Dunlop's view; also to study the influence of the ingestion of oxalic acid in foods, and the physiologic action of soluble oxalates in producing symptoms of the "oxalic-acid diathesis." Oxalic acid and its salts are widely distributed in foods. Some of those which are rich in oxalic acid are spinach, rhubarb, figs, cocoa, tea, coffee, potatoes, beets, beans, plums, tomatoes and strawberries, while those which contain little are peas, asparagus, cucumbers, mushrooms, onions, lettuce, rice, cauliflower, pears, peaches, grapes, melons, and wheat and oats flour.

Dr. Baldwin's observations show that in health the amount of oxalic acid excreted varies with the amount ingested in the food. This tends to prove the accuracy of Dunlop's view. Opinions have differed on this subject. Men fed on a milk diet, and dogs fed on a meat diet alone, do not excrete oxalic acid as a rule, although exceptions have been claimed to occur. Baldwin's experiments were made on dogs and are related in detail. The author's conclusions are as follows: Oxalate of calcium may be present in the urine in solution, and conclusions based merely on the presence or absence of crystals are untrustworthy. Quantitative tests are required, and these demand the utmost care. An ordinary mixed diet always contains oxalic acid or its salts, and some of these may be absorbed and reappear unchanged in the urine. The amount excreted fluctuates with the amount ingested, and varies from a few milligrams to two or three centigrams, being usually below 10 milligrams. In health no oxalic acid is formed in the body by metabolism. In certain disturbances of health, characterized by the absence of free hydrochloric acid in the gastric juice, oxalic acid is formed in the organism. This formation is connected with fermentative activity in the alimentary canal. The prolonged ingestion by dogs of large quantities of glucose leads to a state of oxaluria, which is associated with a mucous gastritis. Finally, the symptoms attributed to an oxalic-acid diathesis are not due to the presence in the system of soluble oxalates, but probably

depend on other products of fermentation and putrefaction. It is thus seen that Dr. Baldwin's experiments tend to place the theory of an "oxalic-acid diathesis" in the list of pathologic myths.

The Condition and Future of the Negro.—The question of the best ways of dealing with the negroes of the South has occupied the attention of very many able educators and philanthropists during the past thirty-five years and the solution of the problem is yet far from evident. Recently several observers have been of the opinion that this question would settle itself eventually by the disappearance of the negro, giving as their reason the great mortality of this race from tuberculosis and syphilis and the lessened fecundity because of the prevalence of venereal disease. Professor N. S. Shaler, Dean of the Scientific School of Harvard University (*Popular Science Monthly*, Vol. 57, p. 29), has recently published some interesting observations and comes to somewhat different conclusions as to the future of the blacks. He finds that with the exception of mulattos the negroes of the South are in excellent physical condition. They are of even, serviceable size, dwarfs and giants being much rarer than among whites. The percentage of deformed persons in the country districts is very low and the physical condition is on an average, he believes, better than that of the peasant classes of any of the European nations. This, he thinks, is due to the rigid selection effected when the Africans were chosen for slaves and the care of their bodies during the time of slavery. He considers them a chosen people, well fitted to carry the burden of life. They are laborious and productive up to, if not beyond, the average of man. Attention is called to the fact that no considerable effort has been made by students of anthropology to determine the varieties which exist in our negro population. Professor Shaler believes that they may be roughly classified in several groups. The mulattos, he believes, are comparatively rare, making up not more than one-tenth, possibly as small as a twentieth, of the whole negro population. The pure Africans of the Guinea type make up about one-half of the southern negroes. The men are usually burly fellows, with massive trunks, low noses and protruding jaws. The Zulu type is much rarer. These blacks have in common with the Guinea type the burly form, deep black hue and general form of the features, but their foreheads are fuller and the expression of their faces quite different. They give the impression of vigorous, brave, alert men. A third group has an admixture of Semitic, probably Arabian, blood. They are tall and lean, with slender necks, high heads, thin features and a better form, the nose sometimes approaching the aquiline. Their skin is often as black as that of the Guinea negro, but is a deader black, possibly due to some difference in the cutaneous glands. The mulattos are of feeble vital-

ity, rarely surviving middle age, and Professor Shaler believes that the mixed stock is likely to disappear. The moral and intellectual condition of the negroes, he thinks, is improving. The belief that negroes are sexually dangerous animals is probably founded on imperfect basis of judgment. An offence which would pass unnoticed in a white is widely published because of mob injustice to the negro. On the whole, he considers the negro less dangerous than whites of a like social grade.

Those interested in the negroes will be glad to see such hopeful views expressed regarding them. As Professor Shaler is a Southerner by birth and has lived a considerable part of his life in the South, his opinions are not expressed without a fair basis of observation from which to draw his conclusions. No doubt a more careful study of the races from an anthropologic standpoint would be of much value in helping to solve the questions of the best method of dealing with a class that makes up a considerable part of the population of our country.

An Example of Newspaper Shamelessness.—We recently alluded to the fact that some physicians may secretly encourage newspaper reports of clinics, interviews, etc., and also that despite all attempts to prevent such things others may be made the victims of newspaper immorality. It is easy to blame the physician when one sees a disgusting report in the papers of his work, but if we wish to be just we should first learn the facts in the individual instance, and upon evidence judge whether the disgrace should not be charged to the characterless reporter or to the editors who permit and encourage his work. We reproduce, for instance, some correspondence which has lately been placed in our hands. Reports of one of Dr. Keen's clinics had been published in several Philadelphia newspapers, without even his knowledge. He at once wrote to the editors of the principal newspapers of the city the following letter:

1729 CHESTNUT ST., PHILADELPHIA, October 12, 1900.

To the Editor of the ———, Philadelphia.

MY DEAR SIR: I have been very much annoyed lately at the publication in several of the Philadelphia newspapers of some reports of my clinics at the Jefferson Medical College Hospital without my consent or even my knowledge that they were to be published.

I am perfectly defenceless against reporters, because my clinics are open to any one who comes in under the guise of a medical student, no ticket being required. May I, therefore, ask you kindly to give instructions that no such reports shall be published hereafter? It exposes me necessarily to the suspicion of being privy to them and invites very disagreeable and unfavorable comment from those who do not know me so well as your reporters. The latter are well aware of my aversion to interviews on such matters.

Yours very truly,

W. W. KEEN.

Not for publication.

Silence, or satisfactory answers, was the result in all but one instance:

OFFICE OF THE —,

PHILADELPHIA, October 15, 1900.

Dr. W. W. Keen, 1729 Chestnut St.

MY DEAR SIR: Replying to your favor of the 12th, I would state that whenever we have a piece of news referring to a clinic conducted by you we will be pleased to send a good reporter to see you, in order that you may have the opportunity to make any statement regarding same you deem proper. It is our desire to print the news accurately, and in order to guard against errors we will be glad to let you know about stories of the character referred to, before publication. I am sure you appreciate the necessity we are under of printing all the news of the day, but in so doing we are anxious to give courteous consideration to persons directly interested and we are as earnest as are you in the desire that the facts shall be accurately and properly presented.

Yours very truly,

— — —, City Editor.

To this strabismic letter Dr. Keen replied as follows:

October 16, 1900

— — —, Esq., City Editor, —, Philadelphia.

DEAR SIR: I have your courteous letter of October 15. You do not understand, I think, my objections. The fact that your statement of my clinic was quite erroneous is a very minor consideration. What I object to is *any* statement on such professional matters. I always prefer to publish these in medical journals to the profession. Once that they are there, then, of course, newspapers can get accurate statements and make any comment they wish, but when it is reported, as my clinic was in the — some two weeks ago, in a sensational manner, it subjects me, and very properly, to extremely unpleasant criticism. I must beg you, therefore, to excuse me from any publication whatever of this character, and, if you would respect my wishes in this matter not to have any such publication, I would be under many obligations to you.

Yours very truly,

W. W. KEEN.

This frank and explicit letter was followed five days later by the most astonishingly outrageous report in the —, in the yellowest of yellow journalistic style—a rehash of the old material. The insult was made more heinous by flaring pictures of a clinic which was not that of Dr. Keen, and in which an impossible syringe was being thrust in an impossible manner in the middle of the dorsal region of the spine of a newspaper skeleton. With commendable pertinacity Dr. Keen now appealed to the proprietor of this paper which wished so ardently for accurate news, and whose editor had spontaneously promised to consult with the surgeon prior to publication:

1729 CHESTNUT ST., PHILADELPHIA, October 26, 1900.

— — —, Esq., Proprietor of the —.

MY DEAR SIR: I beg leave with this to hand you copies of a correspondence I have recently had with the City Editor of the —. May I also ask you to look on page 4 of the — for Sunday morning, October 21?

I beg to appeal to you as a gentleman for protection against what seems to me to be a flagrant abuse of power on the part of the — in utter disregard of my repeated request. This article was published five days after my last letter, when there had been ample time to think over the matter and, therefore, to act deliberately. This I regard as an invasion of my rights as a private individual.

The blunders and inaccuracies of the article are so glaring that any doctor must simply laugh the article to scorn. Its

being a second publication on the same subject in spite of my polite, but urgent and repeated request, is most obnoxious.

I stated in my first letter to your Editor that, owing to circumstances, I was defenceless against reporters. Am I defenceless against editors as well?

Yours very truly,

W. W. KEEN.

Following this came an answer from the City Editor, explaining that "future stories with which your name is connected will not appear until you have had the opportunity to make such statement in reference thereto as you may desire." To this Dr. Keen again replied: "You *still* misunderstand my objection. I do not wish any 'future stories with which my name is connected' to appear in the —."

And there, for the present, the matter rests—at least until the profession shall organize itself and make its wishes respected.

Palatable Prescribing.—Herman B. Sheffield (*New York Postgraduate*, October, 1900) cites a series of adjuncts that may be used to make medicines palatable to children, giving a number of prescriptions. He gives these rules: Never prescribe medicines unless thoroughly convinced of their absolute indication. If a *placebo* is desirable, employ a palatable adjunct. Never prescribe a preparation requiring a large dose when a small quantity of another proves equally efficient, *i. e.*, use an alcoholic extract or an alkaloid instead of a sirup, tincture or infusion. Never prescribe an offensive, nauseous mixture when a palatable one will be equally serviceable. Never prescribe more than 2 ill-tasting drugs in one adjunct, and do not combine several adjuncts which are likely to disguise each other. [G.C.C.H.]

Postoperative Treatment.—Hunter Robb (*Cleveland Medical Gazette*, October, 1900) reports a series of 114 consecutive unselected abdominal sections without a death, with comments on treatment. For restlessness in the 24 hours following operation, he recommends an enema of 2 ounces milk of asafetida, sometimes combined with a half dram of potassium bromid, to be repeated in an hour if necessary. Morphin should never be used unless all other measures have failed. Its use as a routine measure is strongly condemned. Occasionally great restlessness and pain require 15 or 20 drops of the deodorized tincture of opium, added to the nutritive enemas; exceptionally morphin is necessary. In the 114 cases, 18 patients received tincture of opium by the rectum, 13 cases hypodermic injection of morphin. Strychnin sulfate is given as a routine after every abdominal operation. The patient is given $\frac{1}{60}$ grain by the rectum before she leaves the operating room. When she arrives in the ward she is given $\frac{1}{60}$ grain strychnin hypodermically with $\frac{1}{2}$ grain atropin sulfate every half hour for 2 doses. After this she is given $\frac{1}{60}$ to $\frac{1}{30}$ grain strychnin hypodermically every 3 to 6 hours, according to the character of the pulse. In marked shock the $\frac{1}{30}$ to $\frac{1}{60}$ grain of strychnin is administered hypodermically every half hour in doses until 6 to 8 doses have been employed. If the pulse on the morning after the operation is under 110, as a rule no strychnin is given, but if the pulse is over 120, $\frac{1}{60}$ to $\frac{1}{30}$ grain strychnin is given hypodermically every 3 or 4 hours until the pulse-rate is reduced. In 113 cases strychnia was given hypodermically, the total amount in the whole number of cases being 32.8 grains, the average amount being $\frac{1}{6}$ of a grain. It is only rarely that he uses nitroglycerin. For the tympanites which sometimes occur after abdominal operations, the tincture of capsicum—1 to 2 drops in a teaspoonful of hot water every half hour for 3 or 4 doses—or 15 to 20 drops of the essence of peppermint—will often prove effectual. A turpentine stupe, or a mustard leaf over the epigastrium, is a useful adjunct. If these measures do not relieve the tympanic condition, a rectal tube is introduced high up into the rectum, and allowed to remain for from 15 minutes to half an hour longer, or until the tympany disappears. [G.C.C.H.]

Correspondence.

A PROTEST AGAINST PROCRASTINATION IN APPENDICITIS CASES.

BY EVAN O'NEILL KANE, M.D.,

of Kane, Pa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

FAR too much is said in favor of the so-called abortive treatment of appendicitis and of conservatism in operating. The general practitioner is only too willing to procrastinate and "leave nature to take its course," "the trouble to come to a head," "work its way out," or "scatter." This "conservative" course is most agreeable to patients and friends and leaves the onerous responsibility of urging operation to the surgeon. Granted that the physician who treats with medicine instead of the knife is more popular than the "cutter," that he who is prompt to advise operative interference is feared by the timid, and that nine out of ten of these appendix cases get well anyhow, or somehow, by what is practically a let-alone treatment,—yet is this a safe or honest course? If it is true that nine out of ten do recover (I doubt it), who can with certainty determine which! If sometimes a circumscribed abscess does open into the bowel, or externally, and recovery follows, does this excuse our jeopardizing our patient's life?

Perhaps the physician would not be so likely to delay if he always saw all his more serious appendicitis cases through to the end, or if he were permitted to have autopsies in all fatal cases of peritonitis, obscure typhoid, or obstruction of the bowels. If he were always present when operation is performed, as it so commonly is, as a last resort, or if he could see the postmortem condition, he would be more prompt to urge operation.

I have become disgusted with continually having to be called upon to operate either too late, or when it required every effort of the operator, assistants, and nurses to bring the patient through, when the abdominal cavity was filled with pus, general peritonitis had set in, with sinuses burrowing in every direction, and when the appendix had become gangrenous, or had completely rotted away.

In my opinion delay is never safe and seldom advisable. I have known pus to form outside the appendix 32 hours after the onset of the first symptoms or gangrene to develop almost or quite as rapidly.

Appendectomy can be performed without danger if proper asepsis is procured, and is a simple procedure in the hands of an experienced operator, and hernia should not follow if the incision is properly made. There can be no practical harm done by operating as soon as a diagnosis is made, and to delay in any case of acute appendicitis over 24 hours is hazardous. Even if the physician is in doubt as to the correctness of his diagnosis, a mere exploratory incision will clear up the question and may save the patient from a dangerous operation later. I have only three times operated for a suspected appendicitis in which I have been mistaken in the diagnosis. No harm was done, the diagnosis was cleared up, and in one of these instances there were gallstones removed and in another serious adhesions broken up that would otherwise have been overlooked.

I wish that every tender appendix might be removed as soon as detected. Not only would dangerous consequences be averted, but many a case of obscure dyspeptic trouble would be permanently cured.

The stereotyped clinical picture of appendicitis requires cramps, vomiting, fever, constipation, tenseness of the abdominal muscles, with tenderness over the appendix, and pain after eating. In fact, however, we rarely find all these symptoms present in any one case, and indeed none may have been so pronounced as to have attracted the attention of the patient or his friends, and yet grave mischief may have been going on. Thus in a case for which I was indebted to Drs. Mollhaupt and Wilson, of St. Mary's, the patient had not complained of any discomfort, appearing well up to the time of the actual rupture of a large typhlitic abscess. On operating we found the entire abdominal cavity flooded with pus. The appendix had sloughed completely off, so that an eight-inch-long stomach-worm had wandered out through the opening and lay, still alive, up almost under the liver. The patient, a phlegmatic German, had worked every day without complaint until, on receiving a slight blow upon the abdomen, the abscess burst and flooded the peritoneal cavity. Women often suppose their appendiceal trouble to be some menstrual irregularity.

Recently, in such a case actual obstruction threatened from the lymph exudate about the appendix and the adhesions of former attacks, before the patient could be led to believe that her trouble was not entirely due to a uterine displacement. It would, therefore, be losing valuable time to wait for the development of a complete array of manifestations before advising operation. Each hour would add to the gravity of the existing symptoms and to the chances of fresh complications, while the increasing exhaustion of the patient would also detract hourly from the probability of standing operative shock.

Finally, too much censure cannot be given the common practice of drugging these sufferers into a calm insensibility of pain. The fool's paradise into which an opiate throws these patients, not only hides from the physician the full gravity of the case and obscures the diagnosis; it paralyzes the intestines, allowing them to become hopelessly overdistended with gas and caked together by adhesions. At the same time the patient and his friends, being satisfied by the ease and rest thus afforded, refuse to permit operation until the cold sweat of collapse or stercoraceous vomiting tells of impending dissolution.

NOTES ON MASSAGE IN JAPAN.

By H. C. WOOD, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

As every one knows, massage has been largely practised in Japan almost from time immemorial. In a recent tour through that country one of the most interesting and curious sights that I witnessed was a little "tot" between five and seven years old, with the utmost seriousness and earnestness, and with a marked degree of skill, standing and massaging the age-stiffened trapezius and other muscles of the shoulders of an old grandfather or grandmother squatting before him. The common belief that the blind have in Japan a monopoly of the practice of massage appears to be only so far correct that probably 90% of the practitioners of the art are blind persons, who wander about the streets blowing a peculiar double whistle whose two weird notes may be heard at almost any hour of the day or night, pleading for work and sustenance.

In order to make out the differences between the art as prac-

tised by the Japanese and the Europeans, I ordered a masseur in Yokohama, Tokyo, Kioto, Mianeshita, Nikko, and one or two other places. As was perchance naturally to be expected, Yokohama being simply a foreign excrescence on the Japanese body corporate, the masseur in that city was not blind and seemed simply to be badly trained in the European methods. I could not make out any difference between him and a second-class American masseur.

Kioto is the center of all that pertains to Japanese religion, art or customs, having been the capital of old Japan, and being still the culture capital of the country. The masseur I saw there possessed great skill; his methods, however, did not differ very greatly from those to which we are accustomed except in one motion, which seems to me the most efficient I had ever had practised on me, for the purpose of deep kneading between groups of muscles or of muscles situated much below the surface. The motions were so quick that in the absence of ability to talk with the practitioner it was a little difficult to perceive exactly how they were made, but I finally made out that the procedure might be termed a rolling use of the different joints of the fingers; first, the tip; then the distal intraphalangeal articulation; then the next joint; and then the knuckles applied one after another with great rapidity and force; the maximum of the force sometimes being reached with the second intraphalangeal joint, the knuckles only pressing lightly; in other cases the knuckles themselves giving the main blow. It was apparently when it was desired to penetrate deeply between two closely placed muscle-groups that the maximum force was applied with the second intraphalangeal joint.

One or two somewhat curious differences between the Japanese customs and our own were noticeable. In one of the places a woman, old, blind and ugly, was sent to do the work. The length of the seances seemed to be arranged according to the desire or the ability of the person operated upon to pay, and were remarkably cheap even when the foreign price was demanded. Thus, asking the charge at one of the hotels, before engaging an operator, I was told "Thirty sen," i. e. fifteen cents an hour. On expressing surprise, saying I had always paid forty sen, the man replied, "Oh, yes, that is the price for the foreigner." Not considering myself seriously cheated I paid the forty sen, or twenty cents for an hour of labor sufficiently hard to make the operator sweat freely.

A CASE OF PERNICIOUS HEMORRHAGIC MALARIA, WITH MALARIAL HEMOGLOBINURIA.

By NORMAN P. GEIS, M.D.,

of Brooklyn, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

MRS. M., 31 years of age, had never been ill since childhood, except at the time of childbirth. Although all her five labors were difficult she had no had after-effects, and never had any chills nor fever during these confinements. On August 29, 1900, she had an attack of vomiting with some slight fever, but this passed off the next day. On August 31, at 4 A.M., she was taken with a chill that lasted one hour and required numerous blankets to keep her warm. Fever then came on, and gradually increased till about 12 M., when it reached its highest level of 105.4° F. Sweating began shortly after this, and continued until about 5 P.M., when the temperature fell to normal. On September 1, at 4 A.M., the same symptoms developed as on the 31st, and continued in the same way, except that the fever reached 106° F. I was called

in at 3 P.M. this day, and at that time the temperature was 103° F. and declining, reaching normal about 5 P.M. I ordered 10 grains of quinin sulfate at 10 P.M., and 5 grains at 11 P.M. that night. As she complained of severe pains in her legs and arms I ordered 10 grains of sodium salicylate every fourth hour. The pulse was good, regular, and 80 to the minute. On September 2, at 4 A.M., a chill began, followed by fever and sweating as before, except that her temperature reached 106.4° F. I made an examination of her abdominal organs. The abdomen was not distended, although the intestines contained a fairly large amount of gas. The spleen was enormously enlarged and tender, and the lower border was fully 5 inches below the last rib. The liver extended down 3 inches below the ribs and was only slightly tender. I could not feel the kidneys owing to the enlarged spleen and liver. The bladder was empty. No signs of pregnancy existed. For the last 24 hours she had passed only four ounces of urine, which they had saved to show me. The urine was black, and at the bottom of the glass was a grayish sediment. It had a very strong ammoniacal odor. It was the "black-water urine." Unfortunately the urine was thrown away, so that I could not make a thorough test of it. I ordered quinin sulfate as before, and gave nitroglycerin and caffein citrate in an infusion of digitalis, every 2 hours. The pulse was 90; full and regular. The patient was feeling good. During the remainder of the second day she felt well, but did not pass urine. At 1 P.M. on the third day she vomited a small amount of blood, and shortly afterwards passed about 2 drams of blood from her rectum. There was no chill at 4 P.M.; at 7.15 A.M., I was sent for in a hurry because she was sinking. I arrived just before 8, and found her dead. She was talking and laughing just before she died. I found that the left side of her face was bluish as from a hematoma, but it was only in spots. The anterior side of her third left finger contained blood in the distal phalanges. The husband said he first noticed the marks about 10 minutes before she died. The marks were evidently due to hemorrhages, and I think that the immediate cause of her death was internal hemorrhage.

URIC-ACID ENDARTERITIS AND "SYPHILITIC NEUR- ASTHENIA."

By R. B. BARROWS, M.D.,

of Wilmerding, Pa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

A MAN, aged 33, contracted syphilis 8 years ago; 2 years ago—4 years after his supposed cure—he developed leukoplakia (papulosquamous syphilid) of the inner surface of the lower lip. There was some muscular twitching of the first interossei; he also had several attacks of night headache, with tenderness in the region of the ascending frontal lobe. He was treated for a year with 50 gr. of potassium iodid, and then for about 6 months with 15 gr. thrice daily. Similar symptoms returned last May, with the addition of two attacks of herpetic eruption of the roof of the mouth and a peculiar head symptom. This latter resembled slight bilateral pressure against the temples, about the region of the posterior end of the middle frontal convolution. Mental debility supervened, especially as to memory for proper names, arithmetic calculation, with inability to study, and difficulty in comprehending voice-sounds. The patient was of a hopeless, apathetic disposition. He laughed boisterously occasionally at jokes, feared dementia, and considered suicide a possibility. His appetite was good, his strength normal, he slept well, was slightly

anemic, and his patellar reflex was almost absent. He said that he felt that if he only could get rid of the peculiar feeling in his head he would be all right. The iodid proving apparently useless, he was given small doses of auri et sodii chlorid with some benefit. Finally, on an increase of symptoms the last part of August, he was given 45 grs. of piperazin during 5 days, with complete cessation of all symptoms, even leukoplakia. Some tremor remained, but this was probably due to the tobacco-habit. I suggest that syphilis followed by large doses of potassium iodid predisposes to a uric-acid endarteritis, and explains why specific treatment fails in beginning paresis and tabes; also, why "syphilitic neurasthenia" is so "difficult to treat."

SMALLPOX IN FETUS ABORTED AT THE FIFTH MONTH.

By C. W. RUMMEL, M.D.,

of Webster City, Ia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

MRS. Y., aged 24, married, was never vaccinated, and had had no previous pregnancy. Last menstruation occurred the latter part of February, 1900. On Saturday, June 30, she was taken with severe chills which lasted with varying severity through the next day. She suffered severe headache and lumbar pains. No physician was called, as they suspected the nature of the trouble, her father having just passed through an attack of smallpox, but her people thought she had "a high fever" with and following the chills. On Tuesday, July 3, the eruptions appeared, after which the patient felt improved and was soon up and around. On Saturday, July 21, the patient felt tired and began to have pains. On Monday the pains became worse, especially during the night, but Tuesday she felt better. On Wednesday, the 25th, I was called and found the patient in severe labor-pains. The fetus was soon born and was seen to be covered with an eruption most marked on the face and upper portion of the thorax. There were a few confluent lesions on the face and many of the vesicles still showed distinct traces of umbilication. It might be well to add that a few days before I was called, the health-officer learned that the patient had smallpox and fumigated with formaldehyd—to which fact they ascribed the abortion.

AN UNUSUAL DOSE OF OLEORESIN OF MALE FERN.

By ARSHAG D. MARGOSSIAN,

of Fall River, Mass.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE patient complained of having tape worms for 10 years or more, as far back as his recollection extended. He was treated by several physicians for the same without the least benefit. In accordance with my class-room knowledge, therefore, I concluded to give a trial of "oleoresin of male fern," with the necessary steps taken during the administration of the drug.

It was given in the form of capsules, as this was considered the best method of administration. Ten capsules of one drop each were given—the usual dose. However, this was not a successful treatment as regards the expulsion of the head, which should be the main point in the line of treatment.

In order to reach a conclusion as to the merits and demerits of the said drug, I decided to give a larger dose of unusual amount.

The patient was given a half-ounce at one sitting, which resulted in the expulsion of the head with its entire length within 2 hours' time. I have had 5 more cases since the first one, and reached the same results with the administration of half-ounce doses of the drug itself.

Contrary to the unusual dosage of the drug, there have been no complications, or symptoms of poisoning of any kind whatever.

THE REMOVAL OF HAIR BY THE X-RAYS.

By G. H. STOVER, M.D.,

of Denver, Colo.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

FOR some time I have been seeing reports of the use of the Röntgen-ray for the removal of hair from the skin, all advocating this form of light-therapy for the purpose. My limited but very satisfactory experience in this line has led me to a conclusion opposing the opinions of the writers of the above-mentioned reports. I once made several long fluoroscopic examinations of a young boy, and also made a skiagram; another operator did the same, and some time later it was noticed that the hair on one side of the head, in a strip about half an inch wide, came out. It returned completely after a time. For about a year I was making various experiments with the x-ray, making many skiagrams of my left hand, and also using it as a test-piece in fluoroscopic work; a typical x-ray dermatitis resulted, marked by itching papules, swollen, cracked, edematous skin, and loss of the hair from the back of the hand; I stopped using my hand in the way, and after a while complete recovery took place; there is just as much hair on the back of this hand as is on the other one.

PRIORITY AS TO THE SURGICAL MANAGEMENT OF UMBILICAL HERNIA WITH LARGE RING.

By E. D. FERGUSON, M.D.,

of Troy, N. Y.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

IN the issue of the JOURNAL for October 20, 1900, there is an article by me on "The Surgical Management of Umbilical Hernia with Large Ring," by what I supposed was a new expedient. A letter from Dr. J. F. Baldwin, of Columbus, Ohio, called my attention to an article by Dr. Ch. P. Noble, of Philadelphia, Pa., in the *American Medico-Surgical Bulletin*, of June 20, 1896, on "A Remarkable Case of Ventral Hernia. . . ." In that case Dr. Noble utilized the anterior layer of the sheath of the rectus to bridge across the ring, and though his technic and anatomic description varies from my own, he had the idea essential to the operation, i. e., the closure of the ring with a reflected flap from the sheath of the rectus, and hence he is entitled to priority.

Etiology of "Mal des Bassines."—M. Fabre has recently made clear the pathology of this disease of girls engaged in winding silkworm cocoons. It is a dermatitis caused by a poisonous substance in the urinary products of the silkworm moths. Hypochlorites are suggested to neutralize he poison.

Society Report.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twenty-eighth Annual Meeting. Held at Indianapolis, Ind., October 22, 23, 24, 25, and 26, 1900.

THE Section on Bacteriology and Chemistry met at the Pathological Laboratory of the Central Hospital for the Insane, with the chairman of the section, Dr. Theobald Smith, of Boston, presiding.

Several papers were read and discussed. Among them was one by DR. H. L. RUSSELL, of Madison, Wisconsin, in which he showed the **degree of heat which is necessary to destroy the tubercle-bacillus in milk** without injuring commercially the value of the milk. He also read the report of the Committee on the **bacteriology of milk** in its sanitary relations. As illustrating the peculiar way by which such germs find their way into milk, an incident occurring in a hospital at Leeds, England, was related. The nurses in that institution were in the habit of taking glasses of milk from the pantry up into the sick wards several hours before the milk was drunk. An outbreak of typhoid fever occurred among the nurses. Investigation disclosed the practice to which they had been resorting, and when it was ordered discontinued the epidemic subsided.

DR. V. A. MOORE, of Ithaca, N. Y., related the history of a **diphtheria epidemic** which was started in that city from milk delivered by a dairyman whose family had suffered from acute tonsillitis. The eldest son, who attended to the milking of the cows, had been pronounced well and resumed his regular work, but scientific investigation demonstrated that he still had germs of the disease in his system.

The meeting of the Association was presided over by DR. PETER H. BRYCE, of Toronto, Canada. The sessions were held in the amphitheater of the German House. Addresses of welcome were delivered by EX PRESIDENT BENJAMIN HARRISON, GOVERNOR JAMES A. MOUNT, and HON. ADDISON C. HARRIS, Minister to Austria. The response to these addresses was made by DR. CHARLES A. LINDSLEY, of New Haven, Conn.

The first paper presented at the general meeting was by PROFESSOR S. H. WOODBRIDGE, of Boston, which was the report of the Committee on **Car Sanitation**. The following recommendations were reported in the paper:

1. When a passenger is known to be contagiously ill, he should be isolated in a compartment appropriately equipped and ventilated in such a manner as to separate it from the rest of the car. Through trains should be provided with rooms for the sick as well as staterooms, interchangeable in use.
2. The interior of passenger cars should be plain, finished with hard, smooth and polished surfaces.
3. All furnishings should be as nonabsorbent as possible.
4. Coaches should be furnished with effective means for continuously supplying not less than 1,000 cubic feet of warm air an hour for each single seat and for distributing and removing the air without troublesome draught.
5. The temperature should be regulated.
6. The cleaning of cars should be frequent and thorough.
7. Floors and sanitary laboratory fixtures should be frequently treated with a disinfecting wash.
8. All fabrics in cars should receive sterilizing treatment. All bed and lavatory linen should be thoroughly sterilized in the process of laundering.
9. Sewage tanks and earth closets should be provided under the cars. The practice of disposing of excreta by scattering it over roadbeds is dangerous.
10. Water and ice should be obtained from the purest available sources. The use of tongs in handling ice should be insisted upon.
11. The water tank should be frequently cleansed, and periodically sterilized with boiling water or otherwise.
12. The public should be educated to use individual cups. Paper paraffined cups might be provided by a cent-in-the-slot device.
13. The use of canned goods in buffet car service makes careful inspection of such goods imperative. Fruits and all eatables before and after purchase should be stored with care to avoid all unnecessary exposure to street and car dust.

14. The filthy habit of spitting on car floors should be dealt with in a manner to cause its prompt discontinuance. It should be punished as one of the most flagrant of the thoughtless offences against the public right to health.

15. Station premises should receive attention directed to general cleanliness of floors, furnishings, air, sanitariums, lavatories, platforms and approaches, and should be plentifully supplied with approved disinfecting material.

The recommendations of the committee were concurred in by the Association.

DR. J. N. HURTY, of Indianapolis, said that if the Association would make a vigorous demand for **white blankets for sleeping cars**, instead of colored ones, it would be a great reform. The white blanket would tell its own story. Colored blankets are frequently saturated with filth.

DR. H. M. BRACKEN, of Minneapolis, said that inasmuch as the traveling public pay a good price for Pullman cars, it is only right that the cars should be kept clean and in good condition. The beds are made up, people sleep in them, the next morning the linen is removed, while the mattresses and blankets are thrown into the upper berths and remain there until the next night, then used again. It is not uncommon for people, on entering Pullman cars, to complain of the odor of stale bedding, etc.

DR. C. H. JONES, of Baltimore, referred to **tuberculous patients who travel long distances**. When the greatest care and caution are observed, the blankets used on Pullman cars are now and then spat upon by them. The attendants cannot always be with such patients to cover their mouths with handkerchiefs. Railway managers should be notified of the great danger to the public from this source. When the public is educated in this matter, a great reform will have been inaugurated.

DR. C. P. WILKINSON, of New Orleans, stated that the chief objection to the equipment and furnishings of railway cars is that they are **upholstered with absorbable material**. In the extreme South, rattan and steel springs are now used instead of plush and woolen furnishings.

DR. U. O. B. WINGATE, of Milwaukee, referred to the work that is being done in this direction by the **International Association of Railway Surgeons**, and suggested that it might be well to appoint a **committee to cooperate** with a similar committee of that Association to do further work in car sanitation.

DR. HURTY spoke of one railroad which is now constructing seven cars with perfectly **plain interiors**. The bottoms and backs of the seats can be taken out and thoroughly sterilized at the end of every run.

DR. DOMINGO ORVANANOS, of Mexico City, Mexico, read a supplementary report on **car sanitation**. Boards of health in the territories covered by the Association ought to try and obtain support from the different legislatures so as to make certain provisions obligatory on railway companies, as for instance: (1) The isolation in special cars of any persons suffering from transmissible diseases; (2) to supply guaranteed filters in the tanks of drinking water; (3) the disinfection of bedclothes, hangings, curtains, and towels; (4) all sleeping cars should be provided with small disinfectant stoves for small toilet articles; (5) the absolute prohibition under severe penalty of expectoration on pavements; (6) all railroad cars should be provided with a sufficient number of cuspidors containing a strong disinfecting solution.

New Quarantine Methods and Changes which are Called for in Marine Sanitation.—This paper was contributed by DR. ALFRED H. DORR, of New York City. Contrary to the popular belief, the most careful investigation, both from a scientific and practical standpoint, has demonstrated that the clothing actually worn by well persons is not a medium of infection. This is also true of the cargoes of ships. In making this statement, the author does not mean to imply that infection from these sources is not within the realms of possibility. Evidence was adduced that the cargo of a ship does not act as a medium of infection. If exceptions exist, they have not been revealed to practical sanitarians. Outbreaks of bubonic plague in European and other ports have brought prominently before our notice the question of the transmission of this disease by rats and other vermin. Information on this subject at present is incomplete, although Kitasato and Yersin have demonstrated the presence of the disease in rats during the epidemic of bubonic plague in Hong Kong in 1894. Beyond this, sani-

tarians have but little authentic information on the subject. It is reasonable to believe, however, that in such communities as are found in India and China, where filth, overcrowding, and bad sanitary regulations exist to an extent which is almost beyond belief, that the dissemination of infection is so general that even vermin are involved. In civilized communities, however, where the ordinary sanitary regulations are carried out, the danger from this source would seem to be very limited. No authentic reports exist which show that cargoes of vessels have transmitted bubonic plague through the medium of infected rats or other sources. In the inspection of persons coming from infected ports, the ordinary examination, which includes a statement from the person concerned, is not sufficient at all times to detect mild or ambulant cases. The most practical and important addition to the ordinary method of inspection is the use of the clinical thermometer. This has been in operation for the past two years in New York, and the most satisfactory results have been obtained in detecting mild or ambulant cases. While the essayist is convinced that the maximum period of incubation of yellow fever is five days, there is no doubt but that during the first day or so of the disease, persons affected may present themselves and pass the ordinary inspection. The use of the thermometer at this time, however, will almost always show an elevation of temperature sufficiently high to justify the physician or health-officer in causing a longer detention. The author closed with a reference to the value of modern sanitary regulations.

PROFESSOR F. C. ROBINSON, of Maine, said that formerly a great deal of paper was made from rags, and he was surprised to hear that there was no danger from infectious diseases from cargoes of rags. He believes outbreaks of smallpox and other contagious diseases have been traced to rags.

DR. H. M. BRACKEN vigorously controverted the statement of the essayist that healthy persons are not liable to carry disease in their clothing. Every physician of experience could cite instances of physicians who have carried contagion to healthy people.

The paper was further discussed by DRs. WILSON, MONTGOMERY, the President, LEE, DURGIN, JONES, most of whom protested against the idea that physicians could not carry infection in their clothing.

DR. A. WALTER SUITER, of Herkimer, New York, read the report of the Committee on Cause and Prevention of Infectious Diseases. Reference was made to smallpox, which he said was on the increase, and he cited copious statistics to prove his assertion. He added the pleasing assurance that the death-rate from this malady is decreasing. The latter fact must not be viewed too optimistically because smallpox is certain, if an epidemic of it continues long enough, to develop its greatest degree of virulence. He showed the value of sanitary precautions and of vaccination by citing the fact that Puerto Rico, since the United States has dominated its government, has rid itself of the disease, which before the war was very prevalent in that island.

He also discussed malaria, scarlet fever, typhoid fever, and declared himself a believer in the theory that the germs of malaria are transmitted by mosquitos in many instances.

In discussing typhoid fever he referred to the declaration of Dr. Vaughan, that more than 80% of deaths among American soldiers in the Spanish War were caused by typhoid fever, and emphasized the necessity of cleanliness about military camps. He touched upon bubonic plague, and said he did not anticipate a scourge of this disease here, but urged great sanitary precautions.

Etiology of Yellow Fever.—DR. WALTER REED, of Washington, D. C., read a paper on this subject, which was published in the PHILADELPHIA MEDICAL JOURNAL of October 27.

DR. HENRY B. HORLBECK, of Charleston, South Carolina, read the report of the Committee on the Etiology of Yellow Fever. Reference was made to previous contributions on this subject by the Committee, and a digest given of the labors of bacteriologists who have, during the past 12 months, devoted themselves to the study of the *Bacillus icteroides*. The report closed with the following conclusions from an article by Proust and Wurtz, published September 7, 1900:

1. *Bacillus icteroides* of Sanarelli seems to be the spe-

cific agent of yellow fever. That microorganism injected into certain animals, especially dogs, produces symptoms and lesions strikingly analogous to those observed in man. The toxin of this bacillus produces in animals the same effect as the microbe. The injection of this toxin into 5 individuals reproduced in man typical yellow fever, accompanied by its symptoms and anatomic lesions. The serum of individuals attacked with yellow fever agglutinates cultures of *Bacillus icteroides*.

2. The bacillus has a prolonged vitality both in air and water (fresh and sea). It is certain that it is the same in the soil. Moulds favor its development. These facts confirm conditions that have been known a long time. They explain the reawakening of yellow fever a long time after the extinction of an epidemic, and the longevity of the disease aboard vessels in bad hygienic conditions.

"No new prophylactic measures have come out in this knowledge of the etiology of the disease. As formerly, the prevention of yellow fever consists in applying the measures of isolation and of disinfection, and of improving the hygienic conditions."

While the numerous contributions to the cause of yellow fever are far from being conclusive, the researches made during the last few years furnish matters of information which will be guiding-stars in future investigations.

DR. J. P. BERNALDEZ, of Mexico, spoke of human vaccine as a prophylactic of smallpox, and discussed its advantages and disadvantages.

DR. M. S. IGLESIAS, of Vera Cruz, Mexico, spoke of the elements of defence against infectious diseases at the port of Vera Cruz.

Influence of Temperature on Vaccine Virus.—DR. F. W. ELGIN, of Philadelphia, read this paper. After detailing a series of experiments, he drew attention briefly to some of the lessons suggested by the experiments:

1. Vaccine points are unreliable when stored for any length of time at any temperature.

2. Virus on points may be inert, yet germs charged along with the virus remain active, causing a form of irritation somewhat resembling vaccine vesicles, and known as spurious vaccination.

3. That glycerin will not destroy the extraneous bacteria in lymph when stored at or below the freezing point.

4. That continued exposure of germs to low temperature, when constant, does not destroy their activity, and but slightly decreases their number.

5. Hot, and especially variable, temperatures especially injure vaccine.

6. Hot temperatures increase enormously the number of germs in fluid lymph other than that stored in glycerin.

DR. H. C. H. HEROLD, of Newark, N. J., read a paper on Newark's diphtheria-antitoxin plant. Early in 1895, a laboratory for bacteriologic research with an attendant plant for the application of antitoxin for diphtheria, was established under the jurisdiction of the Board of Health in Newark. This department has been in practical operation for more than 5 years. The author presented the results of the experiment of establishing such a plant, and showed by statistics of greatly reduced mortality from diphtheria by the use of antitoxin, that it is one of the best things the city officials and medical profession of that city have ever undertaken.

The presidential address was delivered by DR. PETER H. BRYCE, of Toronto, who sketched at great length the progress of sanitary science from its birth in the period of the Renaissance down to the present time, and declared that scientific workers ought to take courage from what they have seen accomplished in this century. The address was scholarly, and an admirable compact sanitary digest.

The report of the Committee on Pollution of Water-supply was presented by the chairman, MR. GEORGE W. FULLER, of New York City. The report took the form of records and summaries showing recent progress in the more important branches of the subject. With regard to quality, the water-supply of the future should meet the following requirements: It shall be free, or substantially free, from disease-producing germs. It shall be clear and colorless, containing no noticeable turbidity or vegetable stain. It shall be free from objectionable tastes and odors, as supplied to the consumer. It shall be free from noticeable amounts of dissolved iron, such as unfit it for household use. It shall be free

from excessive amounts of lime and magnesia, such as make water too hard for ordinary use. It shall be carefully examined with regard to constituents capable of dissolving metals used in distributing pipes.

Of the various branches of public works connected with the pollution of water-supply, there is none in which such substantial progress has recently been made as in water purification. Ten years ago information upon this subject was very meager, and comparatively few plants were in operation. During this period English sand filter plants have increased from about 15 to 19 acres, with respective normal capacities of about 4,000,000 and 57,000,000 gallons daily; and the American or mechanical filter plants have been increased from about 12,000 to 90,000 square feet, with respective nominal capacities of about 36,000,000 and 270,000,000 gallons daily. Projected plants for some of the largest cities in the country show that in the next few years there will be very rapid development in the application of both of the leading methods of purification. Of the various processes for the purification of water-supplies, there are two general methods which have shown distinctly their practicability, namely, the English method of slow sand filtration, and the American method, employing rapid mechanical filters. For those waters which never possess more than a slight or moderate amount of turbidity or dissolved vegetable color, the English method is somewhat more efficient, and as a rule it is slightly the cheaper for such waters. For those waters which for long periods at a time contain excessive quantities of either finely divided clay or of dissolved vegetable matter, there is now no practicable method of purification without the use of coagulants and subsiding basins. While coagulants can be successfully used in connection with the English method of sand filtration, the American method, in which coagulants are imperative, yields somewhat more efficient and economical results, as a rule.

Teaching of Hygiene and Granting of Degrees of Doctor of Public Health.—DR. WYATT JOHNSTON, of Montreal, compared methods of hygienic instruction in vogue in the United States and foreign countries, with the result that the showing was decidedly favorable to the foreign countries. He inveighed strongly against the looseness of methods in this country by which men are able to secure positions as health officers or as members of boards of health without having the necessary qualification. Dr. Johnston urged the association to consider this matter and endeavor to arrive at some standard for a purely hygienic education.

DR. L. P. JONES, of Greenwich, Conn., followed Dr. Johnston, and outlined the following **scheme for preventive medicine**:

1. The endowment of a chair of preventive medicine in each of the leading medical colleges of the country.
2. The establishment of an institute, the members of which should be the incumbents of these chairs.
3. An award of prizes by this institute for essays and discoveries of special merit in sanitary science.
4. Establishment of fellowships for a limited number of advanced students.

Disposal of Refuse Material.—This subject was dwelt upon by MR. RUDOLPH HERING, of New York City, who presented a report in which he mentioned the methods for disposing of garbage in the great cities of the world. He referred to the progress made by European cities in this direction, and said that the present status of disposing of garbage and refuse has resolved itself largely into a question of engineering.

DR. JUAN BENA, of Zacatecas, Mexico, dealt with the vice of **smoking among youths**, and offered suggestions as to the means of overcoming it.

Report of the Committee on Disinfection.—This was presented by PROFESSOR F. C. ROBINSON, of Brunswick, Me. From what has been accomplished in this work, the following conclusions seem warrantable:

1. Household disinfection after infectious diseases should combine the use of formaldehyd with other means. It can be safely relied upon for all exposed surfaces, and these only.
2. Formaldehyd requires moisture enough in the air to nearly saturate it for its most efficient working.
3. There is much disagreement among experimenters as to the disinfection of tuberculous matter. One says a 2% solution of formaldehyd disinfects it; another that even a 10%

solution does not. Several say that formaldehyd gas applied as above destroys it; others deny this. Further experiments are needed.

4. Soap is a poor disinfectant, but 1% caustic alkali, or 20% carbonate of alkali, is efficient.

5. Carbolic acid, less than a 5% solution, has little scientific value.

6. The creasotes, as used in creolin, lysol, and solutol, are safe disinfectants.

7. Alcohol at from 50 to 75% has considerable disinfecting power, but not at other strengths.

8. Most metallic salts, except those of mercury, have little disinfecting action.

9. Mercuric chlorid should be used in strength at least 5 to 1000 if tuberculous matter is to be disinfected. A fresh solution is more active than one which has stood for some weeks. The addition of salts does not increase the strength of a fresh solution, but prevents it from losing its strength as rapidly.

10. Bright sunlight kills the tubercle-bacillus in a few hours, and, as a rule, pathogenic bacteria keep their greatest virulence only when kept in the dark.

DR. JESUS CHICO, of Guanajuato, Mexico, gave some **hints about malaria**, from personal observations, saying he did not think the mosquito was as important a causative factor as has been attributed to it in distributing malaria, but in Mexico he thought the injudicious use of tropical fruits played an important role.

MISS HESTER McCLEUNG, of Indianapolis, recounted the **sanitary work of women** in that city.

Report of the Committee to Define What Constitutes an Epidemic.—This was read by the chairman, DR. BENJAMIN LEE, of Philadelphia. In the minds of the public at large, and of many of the profession, the word epidemic still conveys an idea of universal atmospheric contamination. This is to be deplored, because, while on the one hand its use inspires an indefinable horror and creates panic; on the other hand it leads to the disregard of the very precautions which are of essential use in restricting the spread of the contagion, namely, those which should be taken in regard to the person and the excreta of the patient, his effects and his immediate environment. In view of changed views as to the propagation of communicable diseases, the word epidemic has outgrown its usefulness. It has become the means of perpetuating false conceptions, and its official use may be misleading and mischievous. Without attempting any stricter, more comprehensive, or more lucid definition of this word, the committee recommended that, as opportunity occurs in all laws and regulations in which certain executive action is made contingent on the declaration by health authorities of the existence of an epidemic, the phraseology shall be altered by omitting the word epidemic, and in place thereof inserting a brief statement of the condition calling for such action, as for example, "whenever a communicable disease prevails to such an extent, or is spreading with such rapidity as in the opinion of the Board to make it its duty to notify either the general public or the authorities of neighboring towns of the fact that such and such action shall be taken." The report of the committee was adopted and the committee discharged.

Report of the Committee on National Leper Home. DR. H. M. BRACKEN, of Minneapolis, chairman, presented this report. This committee dealt with the desirability of establishing national leprosaria in the United States. The records of Dr. Bracken for certain States, compared with those of Dr. Hyde, are as follows:

STATE.	DR. HYDE.	DR. BRACKEN.
North Dakota.....	2	2
South Dakota.....	...	1
Iowa.....	20	3
Minnesota.....	120	61
New Jersey.....	1	1
Ohio.....	...	1
Pennsylvania.....	6	6
Wisconsin.....	20	7

He presumed that Dr. Hyde's figures for Iowa and Wisconsin are estimated. Probably they are not too high. He has taken only those cases of which a history could be given. It is probable that the 120 cases credited to Minnesota are taken from Dr. Hansen's report. It seems to him that this, too

must be an estimate. If there were 120 cases in Minnesota, the speaker cannot understand why they are not on his records. If there were that many cases in 1888, the number for Minnesota is much higher than he has given, for many of the cases in the official list cannot have possibly belonged to Dr. Hansen's 120. It might appear from the report of cases in the Northwest that leprosy was far more common in Minnesota than in the neighboring State. He can see no reason for this belief, for the lepers in this district are among the immigrants from Norway, Sweden, Iceland and China. These people have quite a representation in all this group of States. He can only attribute the more complete returns for Minnesota to the fact (1) that there has been less agitation against leprosy in this than in some of the neighboring States; (2) that with this lack of agitation against leprosy physicians report their cases more willingly to the State Board of Health, which has endeavored during the last 20 years to palliate the sufferings of this unfortunate class; (3) Minnesota is fortunate in having among its physicians men who are familiar with leprosy, and who are interested in philanthropic work, and these physicians have given material aid to the State authorities engaged in securing a list of all lepers in Minnesota. Several lepers in the Minnesota list give the history of a previous residence in Wisconsin, but their names in not a single instance appear upon the Wisconsin records. Of the 37 living lepers known to be resident in the Northwest, 17 only are in Minnesota, and there is a strong possibility of 2 of these being dead, but he has no positive knowledge of the fact. He does not dwell upon these facts as an alarmist, but simply reminds the Association that leprosy has existed, does exist, and will continue to exist for years to come in all three countries represented in the Association.

Establishment of Leprosaria.—A leprosarium should afford a comfortable home for lepers. This means not only good buildings, but extensive grounds comprising many acres, where the lepers may have liberties and still be in exclusion. The buildings connected with the leprosarium must combine the privileges of a home and of a hospital. Those who have the disease in mild form may need little, if any, medical care. They need comfortable clothing and good food. With those in whom the disease is more advanced, the care should be that of a hospital patient, with medicines to lessen their sufferings and dressings that would commend themselves to any surgeon. A leprosarium should resemble modern colonies for epileptics. It should furnish employment for those who are able to work, and amusement of various kinds for all.

Two of the strongest medical societies in Minnesota have placed themselves on record as favoring the establishment of national leprosaria, also the American Dermatological Association has appointed a committee to determine the best methods to be used in the care of lepers. By resolutions the Association placed itself on record as favorable to the establishment of national leprosaria.

DR. JOHN S. FULTON, of Baltimore, described a suitable dress for defence against infectious diseases.

MR. F. H. NEWELL, Government hydrographer, contributed a paper showing some results of the investigation of stream pollution which has been made by the United States Geological Survey. The Government, realizing the importance of public water-supplies and their conservation and protection against pollution, has established a special division under the title of Board of Hydrography.

Report of the Committee on Animal Diseases and Animal Food.—This was read by DR. D. E. SALMON, of Washington, D. C., chairman. He urged the importance of careful observations being made of glanders, in view of the fact that serum for use in the treatment of many human ailments is obtained from horses. Army horses are peculiarly liable to contract the disease in time of war, on account of the extra exertion and frequent lack of full rations during such periods. He roundly condemned the carelessness of the U. S. Government in the matter of providing skilled and trained veterinarians in the army. He discussed the subject of hydrophobia, and emphasized the importance of active measures looking to the extermination of this disease. He cited statistics of many outbreaks of rabies, and showed the disease to be peculiarly virulent and almost invariably fatal to human beings. Misguided people, who declare there is no such thing as hydrophobia communicated to man from animals, were sternly rebuked. DR. SALMON declares that

their obstructive tactics have wrought incalculable harm in the way of deceiving people into a careless attitude towards this malevolent disease. The Pasteur treatment was highly commended by the committee, which also recommended that the association take steps to enlighten the public on the disease and its treatment, as well as means for its prevention.

Tuberculosis.—The committee made strong recommendations on the subject of tuberculosis, asserting its belief in the theory that the disease can be and is communicated from infected cows through their milk. Here also the committee encountered learned men who controvert the theory, asserting that the difference in appearance of the bacillus of human tuberculosis and that of bovine indicates that the latter cannot communicate the disease to human beings. Bovine tuberculosis is undoubtedly communicable. He inveighed against loose methods prevailing in many creameries by which the milk received from an infected herd is mixed with the general supply of milk on hand; and further, the practice of distributing, without previous sterilization, the waste milk and cream to be used as food for swine was condemned.

PRESIDENT BRYCE added a few terse, vigorous utterances on the subject of the care which ought to be employed in dairies to guard against the distribution of milk infected with tubercle bacilli.

DR. R. M. WOODWARD, of Washington, D. C., gave a resume of the recent foreign work of the Marine-Hospital Service.

DR. F. F. WESTBROOK, of Minneapolis, reported on behalf of the Committee on Transportation of Diseased tissue by mail, recommending that nose and throat specimens be included in one package.

DR. CRESSY L. WILBUR, of Lansing, Michigan, presented the report of the Committee on Demography and statistics in their sanitary relations. He mentioned the progress that has been made in matters relating to vital statistics concerning which the association had acted in the past. He urged the association to stand for united and determined action in elevating the standard of registration laws in this country, and in insuring the practical success of new laws when enacted.

The following resolutions were introduced, discussed, and adopted:

1. *Resolved*, That the Association, recognizing the benefits of medical school inspection, heartily approves the efforts of boards of health and of education directed towards the establishment of systems of inspection. (Offered by DR. ADOLPH GEHRMANN.)

2. *Resolved*, That the Association approves of and encourages all efforts made by governments, whether national, state or municipal, for the limitation of pollution of streams. (Offered by MR. C. MONJEAU.)

3. *Resolved*, That a committee of three be appointed, to be known as the Committee on Uniform Municipal Statistics, to take such steps as may seem practicable towards securing greater uniformity in all branches of municipal accounts, reports, and statistics; and particularly those branches relating to vital and sanitary statistics; said Committee to have power to confer with similar committees from other societies already or hereafter appointed to the same general end, and to report at the next meeting of the Association. (Offered by DR. LEAL, of Paterson, N. J.)

Election of Officers.—The following officers were selected for the ensuing year: President, Dr. Benjamin Lee, of Philadelphia, Pa.; first vice-president, Mr. Rudolph Hering, of New York City; second vice-president, Dr. J. N. Hurty, of Indianapolis, Ind.; secretary, Dr. Charles O. Probst, of Columbus, Ohio; treasurer, Dr. Henry D. Holton, of Brattleboro, Vermont.

Buffalo was selected as the place for holding the next annual meeting. The Executive Committee recommended that the time be fixed during the third week in September, 1901.

Two instruments, which have given great satisfaction in the medical service in South Africa, are the telephone probe and Thomas's tourniquet forceps. One blade of the latter is introduced through a small skin-incision, the vessels being compressed between it and the other blade on the outer surface of the skin.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended November 17, 1900:

Monday, November 12.—College of Physicians, Section on Medicine.

Wednesday, November 14.—County Medical Society.

Thursday, November 15.—College of Physicians, Section on Gynecology.

The Carlisle Indian School has been quarantined owing to an epidemic of measles. About 50 cases have been reported.

The "Divine Healer," Francis Schlatter, was denied permission by the Mayor of McKeesport, Pa., to hold an outdoor meeting in that city.

Gift to a Hospital.—The new Nurses' Home, erected and furnished by Mrs. H. C. McCormick, was formally opened and presented by her to the Board of Managers of the Williamsport Hospital, November 1.

New Dental School.—The heirs and legatees of Dr. T. W. Evans have at last reached an agreement to have the estate settled in Philadelphia. About \$3,000,000 will become at once available for the construction and foundation of a dental institute in this city, as provided for in Dr. Evans's will.

Municipal Hospital.—At a recent meeting of the Philadelphia Board of Health, a communication was received from the Woman's Sanitary League, recommending that Councils be asked to appropriate money for fitting up wards in the Municipal Hospital for the treatment of pay patients with scarlet fever and diphtheria. The communication was referred to the director.

Filthy Streets and Diphtheria.—Dr. J. Howard Taylor, chief medical inspector of the Bureau of Health of Philadelphia, has had his attention called to the condition of streets near Heston School, West Philadelphia, where nearly 50 cases of diphtheria have developed within the last 10 days. The streets have been inspected, and the statement made that the recent outbreak of diphtheria in West Philadelphia was probably due to filthy unpaved streets and back alleys.

The Mutual Aid Association of the Philadelphia County Medical Society will hold its annual meeting November 12 at 8 P.M., at 1627 Walnut Street. Officers for the ensuing year will be elected. The Association has been in existence for 22 years. According to its charter, the object of the Association and the purpose for which it is formed is benevolence, by offering pecuniary aid to the widows and orphans of such members as require it, as well as to such members as from long-continued illness or accident may be compelled to seek such aid. The Association has during the year received notice that it is one of the residuary legatees of the estate of the late Dr. Albert Frické, who was for many years chairman of its board of directors. The amount of this legacy cannot be determined until the adjudication of the executor's account. It will probably be several thousand dollars.

Philadelphia Obstetrical Society.—At the recent meeting of the society on November 1, Dr. B. F. BAER reported a case, illustrating the application and relative advantage of vaginal and abdominal section; also a case of tubal pregnancy, in which tubal abortion was completed, and the tube and ovary of the affected side preserved, the other ovary having been destroyed by advanced cystic degeneration, rendering removal necessary. Dr. FRANK W. TALLEY reported 2 cases, 1 of which was an interesting instance of pyosalpinx. A paper by Dr. JOHN G. CLARK described a unique case of sarcoma of the uterus associated with fibroma of the round ligament. According to the clinical diagnosis, the latter was deemed secondary to the sarcoma, an instance of metastasis; but the microscopic examination of the fibroma proved that the

disease was localized in the tumor itself, it being practically a large uterine polyp. Discussed by Drs. BAER, NOBLE, FISHER, and others.

Vital Statistics of Philadelphia for the week ended November 3, 1900:

Disease.	Cases.	Deaths.
Total mortality		376
Inflammation of appendix 4, brain 8, bronchitis, kidneys 14, larynx 1, heart 2, lungs 34, peritoneum 5, pleura 1, stomach and bowels 18, uterus 2		97
Lungs—tuberculosis of 46, abscess of 1, edema 1		48
Heart—disease of 37, fatty degeneration of 1		38
Marasmus 18, inanition 14, anemia 1, debility 5		38
Apoplexy 12, paralysis 6		18
Diphtheria	120	18
Uremia 8, Bright's disease 7, diabetes 2		17
Carcinoma of breast 1, cheek 1, liver 2, esophagus 1, stomach 5, uterus 1, sarcoma of breast 1, tumor of brain 1		13
Convulsions 9, puerperal 1		10
Casualties		8
Typhoid fever	56	7
Liver—cirrhosis of 4, abscess of 2		6
Old age		6
Brain—congestion of 1, effusion of 1, softening of 3		5
Burns and scalds		4
Alcoholism		3
Cyanosis		3
Croup 1, membranous 2		3
Surgical shock		3
Drowned		3
Scarlet fever	38	1
Pelvic abscess 1, aneurysm of aorta 1, asthma 1, atheroma 1, childbirth 1, diarrhea 1, puerperal fever 1, erysipelas 1, exophthalmic goiter 2, gangrene of leg 1, hemorrhage of stomach 1, hernia 1, obstruction of bowels 2, lead poisoning 1, pyemia 1, rheumatism 1, retention of urine 1, arterial sclerosis 1, septicemia 1, stricture esophagus 1, suicide—illuminating gas 1, teething 1, traumatic tetanus 2		

Pittsburg Academy of Medicine.—At a meeting held October 22, Dr. E. E. MAYER reported a case of **locomotor ataxia** and presented the patient, a street-car conductor. The case was of 2 years' standing and on admission presented practically all the typical symptoms in so severe a form as to necessitate giving up his occupation. Treatment consisted in massage, baths, and various movements calculated to stretch the spinal cord and nerves. He left the hospital after 5 weeks' treatment a cured case, clinically, but, of course, not pathologically. The prognosis is not unfavorable in first and second stages if certain measures are carried out. No internal treatment is used, as it is of no value. Dr. PERTTIN inquired if the so called goat's lymph was of any value. Dr. MAYER said he had used it on a few cases without effect. It contains considerable quantities of bichlorid of mercury and chlorid of gold and sodium upon which its efficiency is supposed to depend. Dr. HECKEL said that goat's lymph bears all the earmarks of downright quackery. Dr. J. I. JOHNSTON reported 2 cases of **orchitis following typhoid fever**, and as to the rarity of the affection mentioned Osler's statistics of 2 cases in 800 patients. They are instances of true typhoid infection, but rarely go on to suppuration. In both of his cases there was a marked febrile disturbance. Drs. ELDERICH, MILLER and BURLEIGH also reported cases of the same nature (posttyphoid), 2 of which broke down and suppurated. Dr. WILLIAMSON reported a case of orchitis in which the testicle remained permanently greatly enlarged, but patient states that it never causes any pain. Dr. MAYER stated that he gathered from Dr. Johnston's remarks that he considered the typhoid bacillus a pyogenic organism. Many authorities do not so consider it, and it is very doubtful if it can produce pus. Dr. JOHNSTON replied that he was not prepared to assert positively that it was pyogenic, but he had come to consider it so. Dr. J. D. SINGLEY said he could not call to mind inoculation experiments carried out for the purpose of proving the typhoid bacillus pyogenic, but the consensus of opinion of the best observers is that it is a pus producer. Dr. Keen's work on the Surgical Complications of Typhoid Fever has directed especial attention to the role of this bacillus. Dr. BURLEIGH reported the case of a **fluctuat-**

Ing tumor appearing over the occipital bone of a young child following trauma, which he believed was due to rupture of membranes over the posterior fontanel. The aspirated fluid resembled cerebrospinal fluid. DR. P. J. EATON reported 4 cases illustrating the difficulty of finding a food which can be digested and assimilated in obstinate cases of gastrointestinal trouble in children. It is a peculiar fact that some cases seem to do well during the hot weather, but so soon as the temperature falls to any extent, they go into collapse and die. In treating these difficult cases, occasionally one is impelled as a last resort to give, say pure cow's milk, after having failed with various low-percentage modifications, and is surprised to find the child digest it and improve at once. There is no hard and fast rule in feeding which can be applied successfully to every case. DR. ELDERICH emphasized the important part changes in temperature play in such cases. DR. J. I. JOHNSTON reported the case of a child severely burned over a large surface, which had convulsions for 36 hours following. A peculiar papillary rash developed all over the body, which looked and felt like an incipient variola.

NEW YORK.

Dr. Roswell Park, of Buffalo, has been appointed Medical Director General of the Pan-American Exposition, to be held in Buffalo in 1901.

Paterson (N. J.) General Hospital.—The Graham memorial operating pavilion of this hospital, the gift of Mrs. John Graham, of New York, in memory of her husband, has been opened for public inspection.

Revolt in an Asylum.—In the State Hospital for the criminal insane at Matteawan, N. Y., recently, about 20 inmates revolted, attacked and overcame 8 guards, and made their escape. All were captured within a few days.

Buffalo Academy of Medicine.—At a meeting of the Section of Surgery, held November 5, 1900, DR. GEORGE EMERSON BREWER, of New York City, read a paper on **Differential diagnosis in diseases of the gall-bladder.** The discussion was opened by Dr. Roswell Park.

Suing for Expert Fees.—Dr. R. A. Witthaus, whose bill for \$18,550 for examining the stomachs of Mrs. Katherine J. Adams and Henry C. Barnett, under direction of the district attorney in the Molineaux case, was not paid on account of the small amount in the sinking-fund, will sue the city of New York to recover the full amount of his bill.

Medical Society of the County of New York.—At a meeting held October 22, 1900, the following officers were elected for the ensuing year: President, George B. Fowler; first vice-president, Charles N. Dowd; second vice-president, Irving S. Haynes; secretary, John Van Doren Young; assistant secretary, Fred Palmer Solley; treasurer, John S. Warren.

The Staff of the Buffalo General Hospital has arranged for a series of clinical meetings, to be held in the amphitheater. Interesting medical and surgical cases will be presented from the wards, and also the pathologic material of the hospital will be demonstrated. The first meeting was held November 1, and cases were presented from the wards of Drs. Carey, Stockton, and Park.

Sterilized Milk Depots.—Mr. Nathan Straus, of New York, who has heretofore maintained 2 depots throughout the winter for the distribution of pasteurized milk and milk foods, will, during the coming winter, maintain 4 depots in that city. At all these depots free coupons will be honored, and physicians' prescriptions, to those people who cannot afford even the nominal sum asked, will be gratuitously filled.

Flushing Hospital.—According to the *Medical News* the Flushing Hospital may soon close its doors on account of lack of funds to support it. The hospital authorities have issued a statement, showing that it costs \$14,000 a year to run the institution. The city gives the hospital \$6,000 and about \$3,000 is derived from pay patients. This leaves a

balance of \$5,000 to be raised by subscription. The trustees of the hospital have appealed to the citizens of Flushing to save the hospital.

Victim of Christian Science.—Faith in christian science is alleged to have been responsible for the death of Mrs. Augusta Hubbell, of Brooklyn, November 4. An autopsy revealed the fact that her death was due to peritonitis and appendicitis. She refused to have a regular physician called, and submitted to the treatment of two christian scientists. The physician whom the husband finally summoned, said that her life could, no doubt, have been saved, had medical aid been summoned in time.

The Right of Hospital Residents to Vote.—The attempt made in New York to prevent resident physicians from voting under an article of the Constitution intended to exclude paupers, etc., failed. Justice Andrews, of the Supreme Court, before whom the case was tried, decided that the clause in question referred to paupers, patients and other persons who are maintained at the expense of the public. The decision affects over 400 physicians, nurses and helpers in the hospitals of New York City.

The effect of music on the sick was discussed at length at the meeting of the International Metaphysical League recently held in New York. It was said that the therapeutic value of music has passed beyond the experimental stage and is no longer a mere theory. So many and varied are the natures of the diseases influenced beneficially by it that it is impossible to draw the line and say that it is better for this or that disorder, for music acts directly upon the mind, and mental states are mirrored in the flesh. We do not claim music to be a cureall, but an adjunct, and as such it should have an honored place in the homes of those who would heal, in the hospitals, sanatoriums, and prisons.

The New York Obstetrical Society.—At a meeting, held October 9, DR. JOSEPH BRETTAUR demonstrated a specimen of **lymphosarcoma** of the intestine, in which the diagnosis lay between intestinal and ovarian growth. At the operation the mass was found to be a coil of small intestine, adherent to other coils and omentum. The mesentery was infiltrated, likewise the retroperitoneal glands. The glands were removed with difficulty, 20 inches of intestine resected, after which a Murphy button anastomosis was established in the usual way. The woman did well for 24 hours, but died 50 hours after the operation. The autopsy showed perfect anastomosis, no signs of peritonitis, but signs of hemorrhagic nephritis. The most interesting feature of the case was the entire absence of any subjective symptoms, pointing to a disease of such a serious nature.

DR. H. N. VINEBERG presented a specimen of **fibroid uteri** removed from a patient in whom the menstrual flow has persisted after supravaginal hysterectomy. The patient was 34, had had one miscarriage, and was operated upon one year ago, at which time the uterus, with the fibroid and adnexa, was amputated just above the vaginal insertion. Recovery was satisfactory. Since the operation was performed, there has been, each month, a slight flow, lasting about a day. Examination showed everything to be normal. In the absence of ovaries and tubes, this persistence of menstruation is of interest, and, furthermore, the patient suffers from the usual phenomena of the artificial menopause. DR. H. J. BOLDT, in discussion, said that when the tubes, ovaries, body of the uterus and greater part of the cervix were removed, "menstruation" was impossible, and the "menopause changes" were the same as if the cervix had been removed as well. DR. E. E. TULL, in order to lessen the symptoms, of the menopause, advised leaving at least a portion of the ovary, a proceeding which he had used successfully.

DR. GEORGE L. BRODHEAD read the paper of the evening entitled the **Treatment of persistent occipito-posterior positions of the vertex.** He said, for convenience, all cases may be divided into 3 classes. The first class will include cases in which the vertex is above the brim of the pelvis, the second, cases in which the vertex is engaged or occupies the pelvic cavity, but is not yet at the outlet, and the third, cases in which the vertex has reached the outlet, and is pressing upon the peritoneum. The first class of cases, in which the vertex in posterior position remains above the brim, is met with far less frequently than the other two.

Among the operative procedures which have been advocated are the following: (1) Rotation of the head and body forward by external manipulation with the subsequent application of forceps; (2) rotation of the head to anterior position by internal manipulation followed by forceps; (3) the application of forceps without previous attempts at rotation; and (4) internal podalic version. Early in labor, with membranes intact, the rotation of the occiput anteriorly by external manipulation might be successfully carried out, but where labor has been in progress for many hours, whether the membranes are ruptured or not, rotation is accomplished only with great difficulty if at all. No rule can be laid down in these cases for one or the other method of treatment, nor can it be said that either method is inadmissible in all cases. For men of comparatively small operative experience, he believes that version not only in occipito-posterior, but in occipito-anterior positions as well, is a safer operation for the mother than high forceps. The fetal mortality on the other hand will be higher with version than with forceps rightly used. Operators of considerable experience may under deep anesthesia attempt to rotate the occiput to the front by the introduction of the hand into the uterine cavity. Failing in this, forceps should be applied to the head in the posterior position, by the so-called pelvic application, and the head extracted. The high forceps operation, in these as in all other cases, is always to be undertaken with a proper appreciation of its difficulties and dangers. Failing to deliver by forceps, the child being alive, version, of course, is the other alternative. But, in cases where there is but little amniotic fluid left and the uterus is tightly contracted about the fetus, the careful tentative use of the forceps is to be preferred to internal podalic version. In many cases of the second class the failure of the head to rotate and advance seems to be caused by imperfect flexion. During each pain, therefore, the forehead may be pushed upward, in order to increase flexion and bring the occiput lower down. Should further assistance be indicated the forceps is to be used. In the great majority of occipito posterior positions rotation is spontaneous, and the normal mechanism is that of rotation from posterior to anterior position. Although the occiput usually rotates forward, the exceptions to the rule are so numerous that one must consider carefully the treatment to be followed in such cases. It will be generally conceded that the birth of the head in the occipito-posterior position, even where it is accomplished with great difficulty, is attended with much greater danger of laceration of the soft parts than is the case with the occiput to the front, and that it is difficult to extract the head if it remains in posterior position, and in some cases impossible without great injury to mother and child. In all cases, then, with the exception of some multipara, it is desirable and indeed necessary in the best interests of mother and child to bring about in some way the forward rotation of the occiput. This can best be done by the use of forceps. The conditions which should be fulfilled before the operation of rotation is undertaken are these: (1) The head should be as well flexed as possible; (2) the vertex should be well down in the pelvis and preferably at the vulvar outlet; (3) the membranes must be ruptured; (4) the cervix should be fully dilated or dilatable; (5) the bladder and rectum should be empty; (6) last, but not least, the operator should be positive of his diagnosis of position. Whenever it is possible, the patient should be placed upon a table, but where inconvenient the buttocks should be brought to the edge of the bed. The Tucker solid-bladed forceps is the best for the operation of rotation and subsequent extraction. The writer then reported 8 cases in which rotation had been performed easily and safely, with perfect safety to the child in all, and with but one extensive laceration of the soft parts, due to edema of the vagina and perineum, the laceration taking place before and after rotation had been accomplished.

Dr. E. A. TUCKER said in discussion, that the practice of rotating with forceps would have been considered malpractice a few years ago. He had not seen a textbook which made the direct statement that the head could be rotated with forceps, with safety to mother and child. Yet this procedure is being repeatedly done by our best operators. By "persistent" he understood those cases in which the occiput came down posteriorly and remained so unless some kind of operative interference was used. He considered that an important advance in operative obstetrics had been made, in

recommending forward rotation with forceps. In his opinion, the soft parts were more often injured by waiting too long than by the application of the forceps. Where all the parts had already become edematous, laceration took place with or without forceps. If the operation of rotation is performed before edema takes place, injury will not result.

NEW ENGLAND.

The will of the late Jonas G. Clark, of Worcester, Mass., who founded Clark University in 1889, was filed in the Probate Court of that city the other day. The entire estate is left to the university, provided the people of the city raise a fund of \$500,000.

CHICAGO AND WESTERN STATES.

Diphtheria.—St. Louis reports 393 cases of diphtheria in the heart of the city.

The Deaconesses' Hospital, Seattle, will soon be opened. It is a substantial four-story building, erected at a cost of \$35,000, and will be equipped according to modern methods.

Bequests to Charity.—By the will of the late John Gallagher, of Chicago, St. Joseph's Providence Orphan Asylum, and St. Mary's Training School for Boys each received \$20,000.

Rush Medical College, Chicago, is to have a new \$80,000 building, for which Dr. Nicholas Senn has just given \$50,000. The new building will be principally used for clerical purposes and will be named Senn Hall.

To Make Vaccination Compulsory in Colorado.—An ordinance may be added to the laws governing the city of Denver, Col., making it compulsory for adults to be vaccinated. At present the law only pertains to children.

An Osteopath Fined.—The osteopaths have lost the first battle waged against them in Wisconsin. Dr. Thompson, an "osteopathic physician" of Milwaukee, was recently fined \$50 and costs for practising medicine without a license. The case will be appealed.

Fresno Hospital Burned.—The county hospital at Fresno, Cal., was completely destroyed by fire, October 18, the loss, being about \$30,000, was fully covered by insurance. No lives were lost, but it is feared several patients who were in a critical condition may die from shock.

Milwaukee Hospital.—By a clause in the will of John Plankinton it is possible that the Milwaukee Hospital will inherit an estate worth several million dollars. This inheritance is contingent upon the extinction within 3 or 4 years of two branches of the testator's family.

Chicago Ambulance Corps.—In February, 1900, this corps, numbering 54 men, went to South Africa to aid the Boers. Of this number 4 were killed, 3 were taken prisoners of war, 3 escaped from prison, and 3 are still missing. The surviving members have arrived at Trieste, Austria.

Metropolitan Medical College.—True bills have been found by the federal grand jury, against James Armstrong, Thomas Armstrong, and John H. Randall, officials of the Metropolitan Medical College of Chicago, known as a diploma mill, charged with using the mails to defraud. The accused are at liberty under bond.

Smallpox Among Indians.—Smallpox has broken out in a number of Indian reservations in the West. The Indian Bureau has forwarded vaccine virus to the various agencies. Lieutenant-Colonel Randlett, in charge of the Kiowa Indian Agency, at Oklahoma, telegraphs that smallpox is epidemic on the Wichita Reservation, and that 50 cases have occurred among the children at the Riverside Indian boarding school on that reservation. The disease also has appeared at the Cache Creek Mission, and the St. Patrick Mission, on the Apache, Kiowa, and Comanche reservations. No deaths have been reported thus far, and no alarm is manifested by the Indians. The disease has also appeared in Idaho and Washington.

Ventilation in Theaters.—Complaint has been made to the Chicago Health Department that many of the city theaters are in an unsanitary condition, particularly the dressing-rooms, many of which are almost without ventilation. The department has made an investigation, and found the complaint, in the main, correct. The members will endeavor to have the evils remedied.

The Detroit Medical Society meets every Wednesday at 8.15 P.M., in the Valpey Building. This society is the product of a genuine desire for a more united profession and of honorable means to secure it. It possesses the enthusiasm of recent organization, the strength of a membership of 300, and a definite purpose to do something for its members. It is distinctively a Wayne County society, but regular physicians in good standing, residing out of the county, are solicited to join.

Hygeia Medical College.—According to the *Cleveland Journal of Medicine*, a curious suit will shortly be tried in a justice court in Cincinnati. The Hygeia Medical College of that city has long been having trouble with the State Board, because it was unable to show that it was properly equipped as a school of instruction in medicine. Now one of the lecturers in said college, Dr. O. J. Hensler, has sued the institution for \$260 of unpaid salary with interest. The State Board when it examined the "college" building found very little property of any kind therein.

Testimonial Banquet to Dr. Christian Fenger.—Dr. Christian Fenger, professor of clinical surgery in Rush Medical College, of Chicago, was given a banquet at the Auditorium, November 3, by the profession. The occasion was the sixtieth birthday of the guest, and the entertainment was under the auspices of the American Medical Association. Over 500 guests were present, representing medical societies of Philadelphia, Cincinnati, Louisville, St. Louis, St. Paul, and other cities. Dr. C. A. L. Reed, President of the American Medical Association, of Cincinnati, acted as toastmaster, and Dr. W. W. Keen, of Philadelphia, was selected to present a loving-cup to Dr. Fenger. Then followed "The Physician as a Leader of Men," by Dr. Edwin F. Ricketts, of Cincinnati; "The Physician in Times of Plenty," Dr. W. H. Earles, of Milwaukee; "The Physician in Times of Adversity," Dr. J. M. Mathews, of Louisville, Ky.; "The Physician as a Scientist," Dr. N. Senn, Chicago; "The Physician as a Good Fellow," Dr. C. A. Wheaton, St. Paul, Minn.; "The Physician in Times of War," Dr. C. B. Nancrede, Ann Arbor, Mich.; "The Physician in Times of Peace," Dr. William E. Quine, Chicago; "The Period of Awakening and the Period of Progress," Dr. Christian Fenger.

In acknowledging the receipt of the loving-cup, Dr. Fenger said: "You have certainly passed far beyond any ambition that I ever had. Your gift will make what work yet remains to me pleasant, and when this work is finished I shall be contented in looking back to your kindness tonight, and shall feel that I, perhaps, have not lived in vain. The chief value of this honor to me is the kindness of heart which inspired the gift. For this token of friendly love I wish to express my heartfelt thanks."

Dr. Fenger was born in Copenhagen, Denmark, November 3, 1840. While still a medical student in 1864 he served as surgeon in the war between Denmark and Germany. He received his diploma in 1867, and was for 2 years assistant in Wilhelm Mayer's ear clinic in Copenhagen. During 1868 and 1869 he was an interne in the Royal Friedrich's Hospital, Copenhagen. At the outbreak of the Franco-German war he became surgeon in the Red Cross ambulance corps and served in that capacity throughout the war. From 1871 to 1874 Dr. Fenger was prosector, and during 1873 and 1874 privat-docent at the Copenhagen City Hospital. In 1875 he went to Egypt and was a member of the sanitary council and surgeon to the Khaliifa district of Cairo. In 1877 Dr. Fenger came to Chicago, which has since been his home. In 1873 he became a member of the attending staff of the Cook County Hospital; in 1880 curator of the Rush Medical College Museum; in 1884 professor of clinical surgery at the College of Physicians and Surgeons; 9 years later professor of clinical surgery at Chicago Medical College; and in 1899 he was appointed to the chair of clinical surgery in Rush Medical College.

SOUTHERN STATES.

The Josiah Simpson Hospital, comprising 37 buildings at O'd Point Comfort, Va., in which more than 2,000 sick and wounded soldiers were cared for during the Spanish-American war, has been sold at public auction.

Smallpox in Kentucky.—In Catlettsburg, 25 cases of smallpox are reported and there is one case at Denton. The president of the State Board of Health has placed Morgan County under quarantine because of smallpox at Caney.

Quarantine Continued.—The summer quarantine in Florida generally terminates at midnight on October 31, but according to an order issued by the Florida State Board of Health the quarantine restrictions will be continued until further orders.

The Right to Inspect.—A local meat-packing company of New Orleans has instituted suit against the New Orleans City Board of Health to restrain that board from inspecting their pickled goods, claiming that according to law fresh meats only are subject to inspection.

Smallpox has reappeared in Washington, D. C. Dr. Newbern, of North Carolina, recently appointed to service in the Quartermaster's Department of the army, is the victim. He was promptly removed to the smallpox hospital and there is no fear of the spread of the disease.

Medical Inspection for Public Schools in Washington.—At the last regular meeting of the Board of Education in the District of Columbia, the Committee on Sanitation recommended that medical inspectors be appointed for each school division at a salary of \$500 per annum. The recommendation was endorsed by the Board and will be urged upon Congress.

Correction.—Dr. B. L. Hardin, of Washington, D. C., writes: I would like to make some corrections in the last Washington note published, referring to the aneurysm reported at the Medical Society by Dr. Johnston. The injections used were gelatin—not glycerin—and the amount of silver wire introduced was 10 feet, instead of 12 inches. Dr. Finney, of Baltimore, did the operation, and I think he ought to be given credit for it.

The Virginia State Board of Health was established by Act of the Legislature February 13, 1872, and the following were appointed by the Governor to constitute the first board: Drs. James L. Cabell, Loudon B. Edwards, J. W. Lawson, George Ross, L. S. Joynes, and J. Grattan Cabell. Of these members there are at present only three living. Dr. Edwards has the unique distinction of being a continuous member of this board from its organization up to the present time.

Orleans Parish Medical Society.—October 27, Dr. E. L. McGEHEE reported a case presenting obscure nervous phenomena, simulating latent tuberculous meningitis following normal labor. The case has baffled treatment and is gradually approaching exhaustion. Dr. J. LAZARD reported a case of spinal anesthesia with cocaine for operation on fistula in ano. Sufficient anesthesia was obtained—although not complete—but severe headache and vomiting intervened, which was attributed to the loss of about 25 minims of cerebrospinal fluid. Dr. J. BARNETT reported a case of severe septicemia apparently cured by injections of antistreptococcic serum.

CANADA.

Gift to Hospitals.—At the annual meeting of the Lake of the Woods Milling Company recently in Montreal, \$2,500 and \$500 were voted to the Winnipeg General Hospital and St. Boniface Hospital, respectively.

New Hospital at Toronto.—The Anticonsumption League offers to raise \$30,000 by popular subscription, if the city will provide \$30,000, and then Mr. Gage's offer of \$20,000 will be ample to proceed with the building of a hospital of 100 beds. A suitable site has been procured about 9 miles from the city.

Queen's College.—Dr. Fife Fowler, for 50 years connected with the Medical Faculty of Queen's, has resigned the Professorship of the Practice of Medicine. He will retain the honorable position of Dean of the Faculty.

Disease Among Indians.—It is reported that whole tribes of Indians in British Columbia are being decimated by a disease similar to scurvy. Out of a tribe of 100 Indians 33 males died in 2 weeks, and many others are said to be in a deplorable condition.

MISCELLANY.

Plague in Alaska.—Stories of the sufferings of the plague-stricken natives of the Yukon have reached Dawson by travelers. At Holy Cross 60 patients are reported to have died.

Smallpox.—The British consul at Guayaquil, Ecuador, confirms the report of a smallpox outbreak at that place, but says the disease is not epidemic, though it is spreading among the children.

Obituary.—WILLIAM ARTHUR ZADRISKIE, of New York, October 27, aged 42.—EDWARD ADDISON HERVEY, of Rossville, N. Y., October 26, aged 77.—WILLIAM T. PRENTISS, of Lewisport, Ky., aged 73.—G. W. ROTHWELL, of Sedalia, Mo., aged 88.—LOUIS W. READ, of Norristown, Pa., October 31, aged 72.—JOHN G. DAVIS at Manila, P. I., November 1.—W. L. MAY, of Crawfordville, Ind., October 24.—M. W. KELIHER, of Pawlucket, R. I., October 31.

Health of Soldiers in the Philippines.—The War Department has made public an order issued by General MacArthur looking to the protection of the health of the soldiers in the Philippines. This recites that 50% of the sickness of the army is avoidable by sanitary precautions, the most important of which are the boiling of all drinking water for not less than 20 minutes and the adoption of the strictest cleanliness as to camps, quarters, kitchens, and cooking utensils. Proper regulations are prescribed to insure the adoption of these precautions.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Marine-Hospital Service, during the week ended November 2, 1900:

SMALLPOX—UNITED STATES.

Hardships of Campaigning in the Tropics.—According to the New York *Evening Post*, not all the story is told of the hardships of campaigning in the tropics with an army recruited from the temperate zone by the list of killed and wounded or of dead from all causes. Just as some of the most unwholesome places on the map show the most insignificant death-rates, the inhabitants dragging themselves about with difficulty and unfit to carry on any persistent work, but not ill enough to die, so the morbidity in an army often speaks more loudly than its mortality concerning the conditions surrounding it. The records at the War Department on the subject of discharge for disability are very unsatisfactory. Of 65,000 enlisted men in the regular army for the year ended June 30, 1900, 34% were invalided. Of the 31,000 enlisted men in the volunteer branch of the service the percentage of discharges for disability was .8%, omitting the Puerto Rico regiment, which had a larger percentage of discharges for inability than any other single regiment.

Changes in the Medical Corps of the U. S. Army, for the week ended November 3, 1900:

MITCHELL, L. T., acting assistant surgeon, will proceed to Kaltag, Alaska, for the purpose of relieving Acting Assistant Surgeon R. J. Marsh.

MARSH, R. J., acting assistant surgeon, will return to the post of Fort St. Michael for duty.

WADSWORTH, S. H., acting assistant surgeon, is granted leave of absence for 1 month, with permission to visit the United States.

WELLS, Captain GEORGE M., assistant surgeon, is relieved from duty at the post of San Juan, P. R., and will turn over all public property and other accountability to Major P. E. Egan, surgeon.

EAGAN, Major P. E., surgeon, in addition to his other duties, is assigned to duty as surgeon, post of San Juan, and attending surgeon, department headquarters.

WHITTINGTON, WM. L., acting assistant surgeon, will proceed to his home, St. Joseph, Mo., where he will report by letter to the Surgeon-General of the Army, for annulment of contract.

MOLONY, LOUIS A., acting assistant surgeon, will proceed to his home, Washington, D. C., where upon arrival he will report to the Surgeon-General of the Army for annulment of contract or orders.

HARVEY, LUTHER S., acting assistant surgeon, leave of absence for 1 month is extended for 1 month.

EAGAN, Major PETER R., surgeon, is relieved from further duty in the department of Puerto Rico, and will proceed to Fort Douglas.

TENNEY, ELMER S., acting assistant surgeon, is relieved from duty at Fort Douglas, to take effect upon the arrival at that post of Major Peter R. Egan, surgeon, and will proceed to San Francisco, Cal., for assignment to duty with the troops destined for the division of the Philippines, and upon arrival at Manila, will report to the commanding general, division of the Philippines, for assignment to duty.

WALKER, Captain PHILIP G., assistant surgeon, will proceed to San Francisco, Cal., and report by telegraph to the Surgeon-General of the Army for instructions.

KEAN, Major JEFFERSON R., surgeon, is relieved from further duty in the division of Cuba, and will proceed to Fort McHenry for duty.

NEWGARDEN, Captain GEORGE J., assistant surgeon, is relieved from duty at Fort McHenry, to take effect upon the arrival at that post of Major Kean, and will proceed to Fort D. A. Russell.

PILCHER, Captain JAMES E., assistant surgeon, having been found by an Army retiring board incapacitated for active service on account of disability incident thereto, his retirement from active service October 31, is announced.

MENDOZA, F. F., acting assistant surgeon, is relieved from duty at Nuevitas and will proceed to Santiago, Cuba, for duty.

GEDDINGS, E. F., acting assistant surgeon, is relieved from duty in connection with contagious diseases in the department of Eastern Cuba, and is assigned to duty as attending surgeon at department headquarters and assistant to the sanitary inspector of the city of Santiago.

WILSON, RICHARD, acting assistant surgeon, is relieved from the duty of attending surgeon at department headquarters, Santiago, Cuba, but will remain on duty in connection with civil matters in the city of Santiago.

LIND, OSCAR, hospital steward, Fort Columbus, is relieved from further duty in the division of Cuba, and will report to the commanding general, department of the East, Governor's Island, for assignment to duty.

LEONARD, CHARLES L., hospital steward, now at Fort Columbus awaiting transportation to Manila, P. I., on the transport "Kilpatrick," will proceed to Fort Wood for temporary duty, pending the assignment to duty at that post of a hospital steward in place of Acting Hospital Steward Alfred T. Rowe, U. S. Army, recently discharged by expiration of enlistment.

WYCHE, CHARLES L., acting assistant surgeon, will proceed from St. Louis, Mo., to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops destined for the division of the Philippines, and upon arrival at Manila will report to the commanding general of that division for assignment to duty.

Foreign News and Notes.

GREAT BRITAIN.

Lunacy in Scotland.—Reports for 1899 show 15 663 insane persons in Scotland, an increase for the year of 264.

Influence of Liquid Hydrogen on Bacteria.—Experiments have been made which prove that an exposure of 10 hours to the temperature of liquid hydrogen has no appreciable effect on microorganisms.

Hospital Charges Soldier.—A returned South African soldier has made the statement that he was charged for 77 days' hospital stay. This charge is directly opposite to statements of the War Office in seeking recruits.

Conflict of Evidence.—In a compensation case at Wigan, 3 doctors testified that a man died from blood-poisoning following an injury. Another stated the cause of death to be typhoid fever and was sustained by a pathologist.

Insane Jews.—Statistics from the Colney Hatch Asylum show that 21% of all male Jews admitted are subjects of general paralysis, the proportion in other males being only 13%. Paralysis is not more frequent among the females than in those of other races.

Insane Patients in Clinics.—Dr. Whitcomb, of Birmingham, has for 18 years demonstrated insane patients to his classes. Recently a journalist has created great indignation against it among the town people by questioning the propriety of this procedure.

Sir William McCormac has been given permission by the Queen to accept and wear the "Kaiser Wilhelm Commemoration Medal." This has been bestowed on him by the German Emperor in recognition of his services during the war of 1870-71. The medal was instituted in memory of the late Kaiser.

Practice in Anesthesia.—An editorial in the *Lancet* calls attention to the fact that students of medicine are taught but little of the practical use of anesthetics. They are never asked concerning this in examinations and do not appreciate its importance. A plea for more practical instruction is made.

Vaccination Prosecutions.—At the meeting of the Trowbridge and Melksham Board of Guardians held October 17 it was decided that all vaccination defaulters were to appear before the guardians, and if they gave a reasonable excuse why vaccination should not be performed no proceedings would be taken, but if no reasonable excuse could be given the vaccination officer was to be instructed to prosecute.—[*Lancet*.]

Advantages of Circumcision.—Mr. Jonathan Hutchinson recently delivered an address on this subject at the London Polyclinic. The most obvious advantage is cleanliness. Many cases of seborrhea, balanitis, and herpes are prevented. It lessens the danger of cancer in the aged who suffer from phimosis. Syphilis is also prevented. Attention was called to the fact that while gonorrhea is quite as common among Jews as among Christians, syphilis is very much rarer. This must be explained by the absence of the prepuce instead of by greater morality.

Medical Orthography.—The editor of *The Medical Press* is not yet ready to accept American efforts to simplify the orthography of medical terms. "To bid the scholar discard one of the most tangible results of a long and tedious education is about as reasonable as to bid the physician 'to throw physic to the dogs.' To plead that this is prejudice and not reason is deliberately to ignore the fact that most things in this world are decided by custom, *e. g.*, prejudice, rather than by any act of the reason. That the reform for which he (a correspondent) pleads will come to pass at some future time we cannot doubt, but as yet, though the spirit is willing the flesh is weak, and the repulsion which American terminology inspires on this side of the ocean is still strong."

A Noble Death.—We are rightly proud of the fact that the medical profession numbers many heroes among its ranks. It is no uncommon thing for a medical man to lay down his life owing to the exigencies of his profession; but the recent death of Mr. Alexander Stewart Brown, F.R.C.S. Edin., which took place on October 17, deserves special recognition owing to the circumstances which led up to it. A week or two ago Mr. Brown met with a carriage accident in which he injured his spine. In order to recruit his health he set out for the South of France and on arriving at Boulogne he was just getting into the train when he saw a young man with whom he had traveled from London fall off the quay into the water. Mr. Brown at once waded into the water nearly up to his neck, got the man out, and finding that he was unconscious, wet as he was, proceeded then and there to perform artificial respiration. After two hours' hard work Mr. Brown was successful and he continued his journey to Paris. When there, however, he became so ill that he thought it best to return home, which he did, but succumbed to pneumonia shortly after his arrival.—[*Lancet*.]

CONTINENTAL EUROPE.

Mrs. D. C. Erxleben, the first female medical graduate in Germany, received her degree in 1754.

Professor Robert Koch has returned to Berlin after 18 months of travel in studying malaria and other tropical diseases.

Smallpox.—Hemorrhagic smallpox has broken out near Salerno, Italy. Vaccination is being rapidly done to prevent its spread.

The practice of pharmacy has recently been opened to women in Austria. They must be over 16 years of age and in good physical condition.

The birth of a living child 19 minutes after the death of the mother is reported from Germany. The child was completely restored, but died after a few hours.

Trachoma in Prussia.—This disease is on the increase among the school children of Prussia. Extensive measures against it by the State are recommended.

Massage as a separate study has been introduced at the Berhn University. There are 2 courses, one of 6 months for students, and another of 1 month for physicians.

The Swiss Medical Curriculum.—New regulations raise the minimum length of course to 5 years. Most students take 6 or 7 years. Examinations are to a great extent practical.

Increase of carcinoma is engaging attention in Hamburg. In 1872 there was one case in 1,396, in 1898, one in 1,022. An interesting point is that the mortality of males is increasing and bids fair to soon equal that of females.

A Beneficent Tax.—The Russian government, it is said, at the suggestion of the Czarine, has imposed 2 special taxes for the benefit of the Red Cross Society, which it is estimated will yield, \$425,000. One is a tax upon licenses to travel abroad, and the other a tax on railway tickets.

Raw-Meat Cure of Tuberculosis.—After a trial of about 3 months, the institution at Belgium for the purpose of carrying out Richet's alleged cure for tuberculosis by an exclusive raw-meat diet, has been closed. Those in charge assert that there is no efficacy whatever in the method.

Medical Coeducation in Austria.—The admission of women as students to the universities has been causing disturbance. Professor Nothnagel, of the University of Vienna, refused to deliver a lecture while young ladies were on the benches. At Graz trouble was also caused and the lady students retired from the class room. The Senate of the Austrian universities is endeavoring to prevent further disturbance.

Medical Progress in Turkey.—The celebration of the twenty-fifth anniversary of the Sultan's accession to the throne is important in its medical aspects. Medicine is

prominently represented in the new university. The creation of numberless hospitals in the provinces; a maternity hospital at Hasskien; a hospital for children at Chichli; an asylum for the poor; hospitals against the propagation of syphilis in the provinces; an antirabic institute; a vaccinal institute; the institution of local dispensaries—these are some of the evidences of medical progress.

The Descent of Man.—A despatch to *The Sun* from Berlin states that, at the recent congress of German anthropologists at Halle, Professor Klaatsch, of Heidelberg, read a paper contending that the direct descent of man from apes was no longer maintainable. His conclusion was based on the construction of the biceps muscle of the thigh. He contended that it was a mistake to regard man as the most perfectly developed mammal in all respects. His limbs and teeth do not show any high degree of development, and he is superior to other animals only in his extraordinary brain development.—[*Medical Record*]

MISCELLANY.

Another Cancer Cure.—The latest claimant for this honor is the root of the *cynoglossum*. Striking results are said to have been obtained from its use.

Pasteur Institute at Simla.—The Indian Government will give an annual subsidy of £650 for 3 years to the Pasteur Institute at Kasouli. Major Semple is director of the institute.

Health of Kimberly.—The report of the medical officer of health for 1899 has been published. The death-rate was 17 per 1,000 for the first 9 months, and 42.6 per 1,000 for the entire year, including the 3 months of the siege.

Foreign University Intelligence.—Dr. Wauscher has been appointed extraordinary professor of surgery at Copenhagen.—Dr. Tigerstedt, of Stockholm, has been elected to the chair of physiology at Helsingfors.—At Tübingen Dr. Surrey has been chosen extraordinary professor of gynecology.—The successor to Professor Albert in the chair of surgery at Vienna has not yet been chosen. Maydl, of Prague, and Lorenz, of Vienna, are prominent candidates.

Combating Mosquitos.—Experiments are being made by Prof. C. Fermi and Dr. C. Lumbao, of the University of Sassari, Sardinia, to determine the effectiveness of various substances in driving away mosquitos from the human body, and also in killing these insects. But little success has attended their efforts, only a few substances protecting the body for from 1 to 2 hours. It is easier to kill the larva than the adult insect, petroleum being the best substance in the pools, it remaining active for about 6 days.

Obituary.—ALEXANDER S. BROWN, of London, October 17, aged 45.—ARTHUR SYMONS ECCLES, of London, October 22, aged 46.—EDWARD R. B. REYNOLDS, of London, October 20, aged 65.—WILLIAM DYSON WOOD, of Oxford, October 16.—ARTHUR ANDREW JAMISON, of Glasgow, October 17, aged 56.—SIEGENDEER VAN HINKELOM, of Leyden, aged 50.—EUGENE KOTLYAR, of St. Petersburg.—HEINRICH ABEGG, of Danzig, aged 74.—J. H. REDMAN, of London, October 9.—SAMUEL H. SWAYNE, of Bristol, October 12, aged 79.—JAMES WASS, of Edinburgh, October 17.

The Plague.—The steamer *Ben Lomond*, arriving at London, October 30, from the Philippines, had a verified case of plague on board. No new cases are reported at Glasgow. The local government has issued a memorandum setting forth the sanitary conditions which foster the disease. A brief account of the symptoms are given and emphasis laid upon the importance of recognizing those types in which buboes are not found. Constantinople has been exposed to the disease, but no serious outbreak has occurred. A case was discovered on board the steamer *Marienburg*, that arrived at Bremen from Buenos Ayres, November 5. There has been a considerable increase in the mortality throughout India, especially in Bombay and Poona. There seems to be a recrudescence at Patua. An extraordinary rainfall in Calcutta has made conditions worse, and another outbreak is feared. Inoculation against the disease has almost ceased to be practised in Bombay, but thousands are being inoculated in Poona. Calcutta does not use inoculation, but it is popular in the Punjab.

Selection.

THE EXHIBIT OF THE AMERICAN MEDICAL ASSOCIATION AT THE ST. PAUL MEETING.

A MUSEUM of medical and surgical instruments, apparatus and dressings, pharmaceutical preparations, food and drink for the sick and for infants, utensils for chemical, microscopical and biological laboratories, sanitary and hygienic appliances and devices, ambulances, hospital and office furniture, and of the literature of the medical and allied sciences, has for many years been held in connection with the annual meeting of the American Medical Association.

This medical bazaar should be one of the most interesting features of the meetings, where every member can see the newest instruments, and the most recent additions to the pharmacopeia; where he can inspect books, and place his orders for any professional supplies he may be in need of. The time devoted to a careful study of such an exhibition is always profitably spent, as something must be seen which is new to every one. The exhibitor cannot find anywhere a means of advertising his wares which will bring them under the most favorable conditions to the attention of so many medical men from all parts of the United States, at an equal cost. If visited in his office by an agent the practitioner's only wish is to see the back of his unwelcome guest, but while strolling through the exhibit he is just in the humor to examine anything that is of interest.

The privileges offered at each meeting to those whose business it is to supply the profession with its manifold professional needs were gradually encroached upon by those whose chief occupation is to destroy legitimate medicine by scattering broadcast over the land patented and secret specifics, drugs and apparatus, for every human ill. These intruders, with the effrontery of quackery, than which earth knows nothing more brazen, forced their way into this exhibit hoping to find weak brethren, who would blow their trumpets for them and defend them in the lists if need be, because forsooth they had been endorsed by the American Medical Association. Whereas the truth of the matter is, that the Association has never exercised any control over the exhibit, which has always been in the hands of the local committee, to whom it has been a source of considerable income. The money derived from the sale of space has been a very grateful financial assistance to the committee charged with the important and costly duty of properly entertaining the Association. Hence the temptation has always been strong to increase the revenue obtained from the exhibit even at the cost of lessening its value and dignity, by selling space to concerns that had no business there. This sort of thing could go on only to a certain extent when reaction was certain to follow; and it has come in complaints from members of the Association and in threats from houses doing an open and ethical business, that they will not in the future patronize the exhibit unless it is cleansed of this very undesirable element.

If the members of the Association know that all the exhibitors are worthy of their confidence and that everything in the exhibit has been carefully scrutinized by the committee, then it will receive much more attention from the members, and be correspondingly more valuable to the exhibitors than it ever has been. The exhibit at the St. Paul meeting is to be of this character. Nothing can be exhibited here which cannot be advertised in the *Journal of the Association* or in the *St. Paul Medical Journal*. The editor of the *Journal* has consented that all applicants to the local committee for space can be referred to his office, where they will be passed upon, and if rejected there the committee in St. Paul have agreed to abide by his decision. This arrangement is final and it will guarantee to the Association an exhibit without an objectionable feature, and to the exhibitors that they will not find themselves in bad company.—[*St. Paul Medical Journal* for November, 1900.]

2.—Smith opened the discussion on the treatment of internal hemorrhages in the section on pharmacology and therapeutics of the British Medical Association. When in consultation on cases of hemorrhage, the remark is often heard, "We must do something." This is quite true, but let us not do a foolish or a useless thing merely to comply with popular prejudice. Of the vegetable astringents, represented by tannic and gallic acids, suffice it to say that there is absolutely no foundation for the reputation that gallic acid has so undeservedly obtained—not even is it a local styptic. Tannic acid is, no doubt, a local styptic by its albumin-coagulating power. But the careful researches of Stockman have demonstrated the futility of using it as a remote astringent. It is absorbed in the form of alkali tannate, which has no styptic power, as indeed is obvious from its presence in the blood. Without entering upon the difficult question of the action of ergot upon the gravid uterus, the author pointed out that even if we admit as proved the oxytoxic action of a drug upon a large and specialized mass of unstriated muscle under special circumstances, it is unwarrantable to assume that, therefore, it will cause contraction of the unstriated muscular tissue in the walls of the smaller bloodvessels. Moreover, the experimental evidence in support of the proposition that ergot does cause a widespread contraction of the

smaller bloodvessels is contradictory, and it is only by experimental pharmacology that such a point can be settled. Smith suggested the following rational treatment in an urgent case of hemoptysis: 1. Reassure the patient and calm his natural alarm and excitement and that of his friends by a few judicious words and simple directions, and emphasize the fact that hemorrhage *per se* is rarely a matter of urgency. It is curious to observe that gastric hemorrhages, which are often of much more serious import, have not the same depressing effect upon the patient as a slight tinge of blood in the expectoration. 2. Avoid irritation of the gastric ends of the vagus nerve. Therefore, do not administer cold drinks or pieces of ice to patients suffering from phthisis complicated with hemoptysis. Cold drinks irritate the gastric branches of the vagus, give rise to cough, and thus aggravate the bleeding. Moreover, by causing contraction of the bloodvessels of the stomach, they may tend to increase the flow of blood to the lungs, and intelligent patients, the subjects of hemoptysis, usually discover the truth of this by experience, and avoid cold drinks. Allow, on the contrary, warm mucilaginous drinks. An icebag to the outside of the chest is perhaps of use. 3. Keep the patient absolutely quiet in mind and body. 4. Give morphin hypodermically; this is the best thing of all to do. 5. Relieve the bowels freely by magnesium sulfate or by calomel. 6. Let the diet be simple and nutritious, reduce the amount of fluid, and give no alcohol. Dixon spoke of the results of some experiments performed by Brodie and himself on the vascular changes occurring in the lung. He was able to show that all drugs that raise the bloodpressure as a result of peripheral vasoconstriction increase the total blood in the lung, and hence he believes that such drugs are essentially wrong in the treatment of pulmonary hemorrhage. He discussed the value of urethane in hemorrhage of the bowel, showing that by the use of this drug the intestines, stomach, and bladder become completely paralyzed. He advocated the use of suprarenal extract in hemorrhage from the stomach. Kingscote recommended that in cases of internal hemorrhage endeavors should be made to attract the blood to other parts of the body by heat applied to the extremities or mustard to the nape of the neck. Leslie said the most important principle in the treatment of hemorrhage is undoubtedly the lowering of the bloodpressure. Morphin, especially subcutaneously, is by far the most important drug in the treatment of internal hemorrhage. Astringents are distinctly contraindicated in the treatment of hemoptysis. In every case of hemoptysis the patient should at once be turned on the affected side. Wynter has used a solution of sterilized white gelatin in normal saline solution having a maximum strength of 5%, for the purpose of increasing the coagulability of the blood; 250 cc. of this solution were injected at intervals of a week on 10 or 20 occasions, but the quantity injected was sometimes only 100 cc., while a 1% solution was occasionally employed. This method has been employed for the arrest of internal hemorrhage and as a preventive measure in operations on specially vascular organs. [J.M.S.]

3.—Dixon concludes from the study of the vascular mechanism of the testis that the organ is supplied with vasomotor nerves and that it undergoes changes in volume passively with the bloodpressure, and actively as a direct result of vasomotor activity. These alterations, although well-defined, are insignificant in comparison with the changes in other organs such as the kidney. The testis does not necessarily follow the vascular alterations of either the kidney or splanchnic area; thus, after injections of testicular substance the volume of the testis and intestine expands whilst the kidney contracts. On the other hand, after smaller injections of cantharidin the testis and kidney contract whilst the splanchnic area becomes dilated; in contrast to both these nicotin usually produces immediate constriction of both intestine and kidney, but induces dilation of the testis. Of the substances inducing vasodilation of the testis the following are among some of the most defined: cantharidin (late), valerian, gold (late), spermin and allied bodies, caffeine and fresh extracts of testis. The question of "internal secretion" and the significance of a dilated condition of the testis need not be discussed, but it is evident that, as in other glands, an active dilation of vessels will lead to increased activity. [J.M.S.]

4.—Pilocarpin was discovered by Gerrard and by Hardy in 1875, and shortly afterwards 2 other alkaloids (pilocarpidin

and jaborin) were isolated from the mother liquors. Of these latter alkaloids, pilocarpidin had a similar physiologic effect to pilocarpin but weaker, whilst jaborin had an antagonistic effect, resembling atropin in its action. The original source of pilocarpin was the leaves of the true *jaborandi*, but of late years this variety has become extremely scarce, and the leaves at present on the market are those of *Pilocarpus pennatifolius* and *Pilocarpus microphyllus*. The leaves vary considerably in the amount of pilocarpin they contain, rarely more than 0.5%, and sometimes none at all. Therefore, a salt of the alkaloid should replace the galeaic preparations of the leaves. **Pilocarpin** is the principal alkaloid of the series. It yields crystalline salts, and of these salts the nitrate is the most convenient to use in medicine on account of its stability. Jowett has been able to find no alkaloid answering to the description of jaborin in the *jaborandi* of commerce. [J.M.S.]

5.—In Marshall's experiments after the injection of **pilocarpin** the heart beats became slower and the blood-pressure fell, and after a short but variable interval both gradually returned to normal, the blood-pressure sometimes slightly beyond it. During the rise of the blood-pressure the vagus was generally less irritable, but on reaching its normal height it became, for a short time, slightly more sensitive. This effect was produced by an injection of $\frac{1}{2}$ to 1 cc. of a 1 in 5000 pilocarpin solution; such a dose also produces distinct salivation. After somewhat larger doses the heart ceased to beat for a time, and then gradually returned to the normal. After still larger doses the heart was stopped permanently and the respiration was paralyzed. **Isopilocarpin** produced a similar but much weaker effect. **Pilocarpidin** was very slightly active. [J.M.S.]

6.—From experiments with **extractum jaborandi liquidum** (B.P.) Jowett and Marshall conclude that the substance gives only a pilocarpin action. Enormous doses were necessary to produce an effect. The inactivity seems to be due to the absence of pilocarpin rather than to the presence of an antagonistic alkaloid. [J.M.S.]

7.—According to Kingscote, there is only one way of artificially producing **asthma**, and that is to divide the left vagus in the neck and gently stimulate the proximal end with electricity. By this method asthma is produced in the right lung and spasmodic contractions in the right half of the diaphragm. We must look, therefore, for the cause of asthma in some tissue or tissues supplied by the vagi and the sympathetic nerves, or in a lesion of the nerves themselves. There are 3 pretty constant factors in cases of asthma of long standing—cardiac dilation, acute vesicular emphysema, and chronic congestion of the liver. These conditions must be dispersed, in addition to any other causes, in order to cure the patient. Having ascertained the vagal or sympathetic irritation, endeavor to remove it. To reduce cardiac dilation, the Schott treatment is the best; whereas emphysema may be reduced by breathing exercises. [J.M.S.]

8.—In the discussion on **serumtherapy**, Bokenham said the best results from the use of serum would be obtained when serum (whatever its kind) was used early, often, and strong. It was not fair to any treatment to postpone its adoption until the patient was moribund. Early and free use of diphtheria antitoxin did certainly, in the author's experience, enormously reduce the risk, not only of visible paralysis, but also of cardiac failure at a later stage. [J.M.S.]

9.—In a discussion on **diet in the treatment of disease** Campbell said that the food of civilized man had much of its indigestible portion removed, and, furthermore, that it was cooked. It has, therefore, these two characters—concentration and softness. The concentrated state of our food explains the great frequency of constipation among the civilized; because the intestines are not sufficiently stimulated by voluminous contents. The softness of the food leads to defective mastication, and this, Campbell contended, was the chief cause of dental caries and adenoids. Sommerville said in diseases of the stomach one must make an accurate diagnosis, determine what constituents of the gastric juice are increased or decreased, and administer food accordingly, instead of, for example, in excess of hydrochloric acid to feed with proteids principally. In pulmonary tuberculosis the quantity of food ingested should be pushed to a very large degree; appetite here has no relation to digestive power, and on the recognition of this fact the out-

door treatment owes much of its success. In the treatment of fevers, where rapid metabolism leads quickly to degeneration of important organs, care should be taken to replace as easily as possible lost proteid material. Mullick called attention to the necessity of choosing the albuminates when we desire to check the waste of nitrogenous tissue, to regulate oxygen absorption, to build up muscular and nerve energies, and to create fat and heat. The use of hydrocarbons is to lessen tissue waste and also to bring about the storage of albumin. The guiding principles in the treatment of all febrile states are: (1) To administer food in the simplest form for absorption and assimilation, (2) to administer food in such a form as will not only build up tissue waste with the least effort, but also to flush out of the system the toxins that have accumulated in the body as a result of the excessive metabolic processes, especially of the albuminous tissues, from the high temperature and also partly from defective digestion. [J.M.S.]

10.—The types of **eczema** met with in gout are, the acute dry, the acute moist, the chronic, and what may be termed the latent. By this last Martyn means a burning, itching, tormenting sensation beneath the skin, with no visible lesion. The **treatment** consists in enforcing a rigid dietary. All those articles that experience has shown to produce dyspepsia must be avoided; alcohol especially must be prohibited. Bismuth and alkalies must be freely given; best for periods of 3 weeks with short intervals. To relieve the intense burning and itching, nothing answers so well as a lotion or ointment containing carbolic acid. The best underclothing is undoubtedly cotton in the cellular woven form or in the form of Lehmann's cotton-wool clothing. Climate in gouty eczema is of great importance. Of all localities the sea is the worst. The diet must be a typical gouty diet with the minimum of proteid and starchy foods, and all those articles that produce an acid fermentation. There are some forms of food that are particularly irritating in eczema and that must be altogether withheld. The forbidden articles include alcohol, all forms of raw or cooked fruit containing much fermentable sugar or acid, especially strawberries, gooseberries, apples, lemons, and rhubarb; and stimulating food. Those drugs that are used as gout specifics never have the slightest influence in controlling or curing the eczema; but, on the other hand, drugs that benefit dyspepsia and increase the alkalinity of the blood, such as bismuth, the alkalies, and the bromides are of real value. The less irritation there is, and the more the eczema inclines to the dry and scaly type, the more will arsenic be found of value. The daily use of some mineral aperient water should never be omitted. The local treatment is very important. For the very acute moist inflammatory type soothing lotions containing lead and opium should be constantly applied. As soon as the irritation begins to disappear, and the exudation lessens, the author always substitutes dusting powder of carbonate of magnesia and fullers' earth. For the dry, irritable type, he finds nothing excels the old-fashioned tar in the form of the liquor carbonis detergens. The great area of the body that eczema so often occupies renders the employment of lotions and ointments difficult and it is in these cases that the employment of baths is so valuable. Gouty eczema in the aged is often benefited by daily sponging with warm sulphur water, and the free use of a dusting powder after drying. Sleep must be procured. [J.M.S.]

11.—From a study of **proteid metabolism in children**, Tanncliffe and Rosenheim conclude (1) that milk-proteid (plasma) is capable of replacing meat as a nitrogenous food in the mixed diet of children according to its nitrogen percentage; (2) that greater increase in body weight took place during the milk-proteid periods in all 3 cases than during the meat periods; (3) that the phosphorus of the milk-proteid is capable of being assimilated and retained in the body. The studies were made on 3 children, 2 of whom were typically healthy and one of whom was badly nourished and just convalescent from pneumonia. [J.M.S.]

12.—In the **medicinal and dietetic treatment of heart-failure in the aged**, Ross believes that the problem, is to see that an aged patient taking a cardiac tonic also gets the wherewithal to renovate the cardiac machine. This is quite apart from the generation of muscular energy, which has its origin in the muscular burning off of fats and carbohydrates with the production of carbonic acid. An accidental observation of Muiret and Combemale led the author to

adopt the plan of increasing the myosin albumin in senile patients who were taking a cardiac tonic. This method gave marked success. The heart, more than any other organ of the body, is peculiarly fitted for and able to effect almost instantaneous metabolic reparation, even under stress of work, provided the material be of proper character and in sufficient quantity. The myosin is obtained from raw minced steak, extracted by cold 0.5% sodium chlorid solution and then curdled out. It is tasteless when so made, and can be put into a rice or custard pudding, into milk, or made into meat panada with egg and cream. The author attaches no importance to stimulant beef teas or extracts containing only excretory extractives, as they tend to call out wear and tear which they are incapable of themselves repairing. The difficulty of gastric fermentation of starchy foods in senile cases is best met for the time being by malted foods such as extract of malt alone, or in combination with cod-liver oil, and, in the case of those who cannot take oil, in combination with bone marrow. Mellin's food, cane-sugar in small quantity, and a limited amount of alcohol, either as such or in an effervescent wine, will be found useful. [J.M.S.]

13.—There are a considerable number of people, sometimes children, but generally middle-aged subjects in good circumstances, who suffer from recurrent attacks of gravel, or who after outbursts of renal colic repeatedly pass small oxalate calculi. In such subjects the prolonged administration of small doses of magnesium, say 40 gr. of the sulfate, given in the afternoon and at bedtime, in a well-diluted solution or combined with some mild diuretic, such as the citrate of potassium, would seem to be a suitable form of treatment. Attention to general health, regimen, and diet must also be kept well in view. [J.M.S.]

14.—Burton-Fanning advocates the term **hygienic treatment** instead of **open-air treatment**. The chief feature of open air is its comparative freedom from micro-organisms, but allowance should probably be made also for the presence of ozone. The view is held by many that some peculiar property belongs to air in motion. Generally speaking, the effects upon a consumptive patient of life in the open air are increased sense of well-being, increased appetite and assimilation, resulting in gain of weight and physical development, reduced frequency and increased strength of the pulse, improvement of nerve-tone, encouragement of healthy sleep, improvement in the quality of the blood, increased activity of the lungs, and comparative immunity from respiratory catarrh. Among other diseases that respond to **open-air therapy** are the other tuberculososes, typhoid fever, smallpox, scarlet fever, measles, whooping-cough, certain nervous diseases, such as neurasthenia, anemia, rickets, marasmus, and diarrhea. Chowry-Muthu said that certain cases of pulmonary tuberculosis are not suitable to be subjected to open-air treatment. These include: 1. The chronic cases that have run a mild course, and in which the system has been vitiated by the toxin of the tubercle bacilli and other pathogenic organisms. 2. The cases in which the stomach is feeble with a tendency to nausea and vomiting, and in which the stomach trouble is much more serious than the lesion of the lung. 3. The cases associated with bronchial catarrh. The speaker referred to the value of inhalations of formalin (igazol) in phthisis, and thought that patients undergoing sanatorium treatment were cured a few weeks earlier after its use than they probably could have been without it. Kingscote said that pure air stimulated the red-blood corpuscles and invigorated the phagocytes, and, therefore, made them better able to combat the bacilli, while impure air did the reverse. [J.M.S.]

15.—The reputed moist character of **Irish weather** has been no hindrance to the successful carrying out of the **open-air method of treatment** in Ireland. There is great advantage in treating patients in their own climate, however. Sinclair believes that, as in every other form of treatment of disease, the adoption of any rigid system, or any empirical rule that necessitates indiscriminately the administration of so many ounces a day of food to every patient must in the long run prove unsatisfactory. In sanatorium practice the idea that must always be paramount is that the reason of the patient's being there is to get well and not to amuse himself. But while this is so it is the physician's duty to map out each patient's life in the sanatorium so that his individual partialities are considered, and if one could find congenial occupation for every patient, the ideal

principle of a "consumption colony" would be worked out. Too much emphasis cannot be laid on the infectivity of sputum. [J.M.S.]

17.—Ewart has administered hydrogen dioxid by subcutaneous injection and he has also given oxygen gas in the same way. The two series of observations show that it is possible to set up a local oxygen emphysema of the areolar tissue without evil result, and that the gas will be gradually absorbed, though the process is a slow one. The diluted hydrogen dioxid infusion is, perhaps, the less risky of the two methods. On the other hand, the oxygen-gas injection is easier to carry out, and the possibility of wounding a vein seems to be its only danger. This may be readily guarded against with sufficient care; and the remote risk is much limited by the preliminary precaution of applying a ligature to the upper part of the limb. The clinical value of the **subcutaneous administration of oxygen** as a general stimulant has yet to be made out. [J.M.S.]

20.—Griffin reports a case of **leukosarcoma of the iris** occurring in a patient 19 years of age. The case was especially interesting because of the age of the patient, most intraocular sarcomas occurring much later in life; also because of the hyalin changes found in the growth. These changes, with its nonvascular character, gave the tumor a dense white appearance. [G.B.W.]

21.—Clark reports a case of **cerebral tumor** accompanied by postneuritic atrophy in the right eye, and choked disc in the left. The symptoms presented led to a diagnosis of tumor situated on the left frontal lobe, limited behind by the ascending parietal convolution and below by the third frontal convolution and the speech-center. The special interest in the case lies in the confirmation of the diagnosis by postmortem and in the absence of serious symptoms until within 48 hours of death, and in the microscopic examination showing the tumor to be a psammoglioma. [G.B.W.]

2.—Ewart believes that the systolic action of the heart is mainly constrictive; it approximates almost every point in the heart-wall to the septum. Locally, slight shortening of the longitudinal fibers must take place to adapt at every point the considerable convexity of the heart-wall to the

length of the septum; but there are 3 situations at which a perceptible shortening occurs, namely, the anterior wall of the conus arteriosus, the muscoli papillaris, and the auriculoventricular orifices, which are carried downwards and backwards, thereby aiding auricular aspiration and ventricular compression. Whatever the precise mechanism of the mitral closure may be, it must be credited with considerable adaptability to varying conditions. The normal mitral closure is due to the contraction of the orificial fibers and to close adaptation under bloodpressure of the valvular membranes. The mitral membrane is not made up of separate flaps, but is a single membrane extending continuously all around the orifice. It forms a shallow wide-mouthed funnel, of which the narrowing funnel of stenosis is merely an exaggeration. Nevertheless the anterior and posterior flaps are well individualized both in their anatomy and in their function. The great anterior flap fulfils various purposes, but it never ceases to be a ventricular partition, and during systole it is kept spread out and smooth. The posterior flap, which forms the greater part of the circular membrane, but is much shorter in the vertical direction than its fellow, is essentially mobile, being attached to the entire length of the fibrous loop and of the contractile border of the ventricular wall. During systole it is folded into numerous pleats like a purse; but the pleating is done not by the pull of a string, but by the contraction of the orificial fibers, and the pleats are arranged by the chordae from below. The stretching of the great flap is effected by its 2 strong diverging chordae and higher up by the 2 mitral insertions which connect it with powerful muscles and with the aortic roots and fibrocartilages; its lower part and its fringe alone are capable of flapping to the extent which orificial space and chordae will allow, but during complete oblitative systole there is neither much space nor much rope, and this flap as well as the posterior flap is drawn almost vertically downwards. The high closure and the low closure of the mitral valve are the two extreme types associated respectively with an uncontracted and a contracted orifice. The first, seen in dilated, in partly paralyzed, and perhaps in some peculiar normal hearts, is relatively precarious. The second, which is distinctive of thoroughly normal and strong hearts, is made doubly secure. Should the systole fail to empty the retromitral pool or to obliterate the muscular orifice, the closure will be almost exclusively membranous. This is the high closure, or purely membranous closure by horizontal adaptation. In the normal type of low closure the orifice is contracted, the membranes are vertical, and they are in apposition not only at their fringes, but over a considerable part of their surfaces, which are pressed back to back and applied to the outer ventricular wall by the intraventricular bloodpressure, whilst their attachments may either meet if the muscular orifice should be tightly closed or be separated by a small wedge of auricular blood, and at the same time bulged slightly upwards by the ventricular blood. This is the perfect and secure musculomembranous closure of a completely contracting and emptying heart. As soon as the auricular systole and the early presystolic contraction of the ventricle have overstretched everything, the powerful and rapid papillary contraction probably takes place simultaneously with the first sound. By this the chordae and their membranes would be stretched downwards and made taut, helping to depress the ventricular orifices. Another important function of the papillary muscles is their share in the production of the first sound, which is largely one of muscular vibration. Not the least of the papillary functions seems to be that of steadying and of adjusting the aorta from below and of providing for its patency. Continuity of muscular fibers across the auriculoventricular groove does not seem to obtain in man. Possibly the regulation of the rhythm may be in part mechanical, and analogous to that of most of our muscular adjustments, namely, essentially myotactic. A different explanation is that by a direct overtension of the heart-wall, its various fibers being unevenly stretched by the growing ventricular charge, and therefore successively excited according to the different length of their course in the ventricle. In both cases the regulation as to time and as to energy of contraction of various parts of the heart would be under the influence of the highly variable scale of internal pressures, one of great delicacy and capable of affording some explanation for the great variations of the cardiac rhythm in health, and for some of its remarkable patholog-

ical abnormalities. The common systolic functional murmurs are still imperfectly explained. Their eventual disappearance suggests that the valvular structures are sound, and that there is merely some muscular or neuromuscular derangement, with temporary failure of orificial closure as a result. Orificial defects may also arise from structural causes. The murmurs are then organic, but more commonly these murmurs are associated with valvular deformities. Leaving aside vegetative valvulitis and ruptured valves, the structural changes at the onset may be so slight as to elude a superficial inspection, and they may produce little more than transient limitations of movement. But, unlike the rheumatic joint, the heart can never be absolutely rested, and if the infiltration is not merely myocardial, but should also affect the valve, it is likely to progress to the verrucose stage, and to those roughenings, thickenings, puckering, and obstructions that we all know tend to leakage by faulty apposition. Myocardial stiffness is one cause of valvular defect and epicardial stiffness is another. Assuming as a common factor in the evolution of early mitral disease into opposite types, the inevitable fibrosis and retraction incidental to all warty valvulitis, the direction of the progressive change will vary with habitual attitude of the valve. If the valve be constantly kept well down in the ventricle, fibrosis and shortening are likely to overtake the chordae. But if from abnormal patency of the orifice the flaps be raised high at each systole, the flaps and not the chordae will be the chief seat of shrinkage. The chordae will be submitted to a systematic elongation at the time when, owing to rheumatic or inflammatory softening, they are most easily stretched, their weakness thus becoming a protection against all danger of stenotic shortening. **Stenosis**, according to this slightly paradoxical view, would be the disease overtaking strong, normally-acting hearts; incompetence the disease of yielding, atonic myocardia. And this, I believe, will agree with your experience of the great prevalence of the stenotic affection, and of its predilection for young and healthy hearts with good cardiac sounds. While normally the auricle is intended to contract independently of the ventricle, in mitral stenosis it permanently invades the upper ventricular space and is in reality an auricle inside the ventricle, and it is thenceforth subject not only to its own contraction, but to that of the ventricle also. The most obvious fact in this condition is the encumbrance of the space of the ventricle. The auricle plays the part of a foreign body wedged into the ventricular orifice, and distending it at the moment when it should be contracting. Great delay must follow, and there is little wonder that an unusually long presystole should be a distinctive, and in the matter of impulse, a tangible feature of stenosis. Of the normal behavior of the mitral valve little is left but the tension of the stiffened membrane by papillary effort, which to the author's mind is a sufficient cause for the loud first sound. In those cases where the ventricle is still struggling successfully, and manages to empty the funnel, the first diastolic bruit is due to the sudden descent of the blood dammed up in the auricle into the capacious funnel. The "rumble" kept up in some hearts throughout the diastole is due to the injection of a strong stream of blood from the often irregular and rough orifice across the stiffened papillary tackle. The presystolic murmur is, the author believes, that of a fluid vein likewise making for the apex. It might be compared to the stream from a syringe forcibly emptied under water, for the ventricle is already nearly full and the chordae less apt to vibrate. Its crescendo character may be explained by the growing pressure of the ventricular orificial presystole upon the funnel. During the presystole, there are 2 streams from the funnel, the auricular systolic pressure preventing, however, much regurgitation, but that as soon as the first sound marks the cessation of the intraventricular flow the reflux is so much increased and accelerated as to cause an audible fluid vein. According to this view there is no absolute reversal of current; some blood was previously being driven back into the auricle, and therefore there need be no interval between the first sound and the murmur. If the contractile fibers of the ventricular orifice had been worn out by the invincible resistance of a permanently distended auricle and funnel some of the murmurs would be obscured. This is precisely the condition observed at the later stages. Not only the presystolic murmur disappears, but with it the second sound at the apex. The influence exercised upon the arterial system is

not limited to the aorta and to its valvular sound, but may be traced in the pulse. The pulse of mitral stenosis is of 2 opposite kinds, according as compensation is perfect or failing. In the former case it closely resembles that of moderate aortic stenosis, and the author believes that it is due to a slight obstruction in the aortic current. In the compensated stage the funnel merely encroaches upon and narrows the infra-aortic space, but when compensation fails, its increasing size sets up a dangerous obstruction. [J.M.S.]

3.—In order to exert any influence on the endocardium in cases of **acute rheumatism**, to prevent or assuage rheumatic inflammation, to remove the products of such inflammation, and to prevent the crippling of the valve we must stop the rheumatism as rapidly as possible, and prevent all aggravation of it by chills. We therefore keep the patient, absolutely at rest in bed; clothe him from head to foot in a warm flannel garment. We further give salicylates in full dose, often with alkalies, and cholagoges in such measure as to cause free evacuations but no diarrhea. The diet is confined to milk and light farinaceous food; no red meat is given for a long time. The patient is kept in bed long after all pain and fever are gone, for it should never be forgotten that the salicylate treatment, while removing pain and fever in 24 or 48 hours, does not remove the rheumatic entity itself after less than 2 or 3 weeks of steady administration. If the mischief in the heart has begun before you see the patient keep the patient most stringently at rest; no raising the head, no excitement; he must have the most perfect physiologic repose you can devise. In order to give any help to the natural powers in their strife with the rheumatic dyscrasia in the endocardium, small blisters the size of a shilling may be applied in the course of the first 4 intercostal nerves, or over the upper part of the chest between the clavicle and the nipple. In order to absorb and remove all inflammatory exudation from the endocardium and valve cusps as early as possible, it is advisable to give iodids and mercury. During the last 15 years Caton has treated 85 cases of valvulitis in hospital on the plan above described. Of these 54 already had signs of cardiac trouble, apparently recent, when they came under his charge; after being subjected to the treatment above detailed, 34 of these left hospital with apparently sound hearts, while 20 had valvular disease. Thirty-one cases came into hospital with sound hearts (or at least having no bruit) and valvulitis occurred in hospital. Of these 27 went out with apparently sound hearts, 3 lapsed into permanent disease of the valve, and 1 remains under treatment. [J.M.S.]

4.—The statement that the relative positions assumed by **culex** and **anopheles** are so strikingly different is erroneous, and it is to be regretted that it has been incorporated in all recent literature on malaria, because it is likely to linger long in the writings of copyists. When Sambon and Low first came to the Roman Campagna this year they observed thousands of anopheles in the houses and stables of intensely malarial places, but none of them ever assumed the position described by the members of the Liverpool Malarial Mission. These anopheles belonged to the species *claviger*. They were usually found in the darkest corners, not infrequently beneath tables and chairs or behind pictures. On painted ceilings they were generally found on the darker colors, which protected them best. A very favorite haunt were the cobwebs, especially in the stables, the ceilings of which were always heavily curtained. But wherever found the anopheles never stood on their heads, but rested on their feet with the posterior part of their body slightly inclined away from the support on which they were resting. The inclination of the body was less when the insect rested on its 3 pairs of legs and formed a maximum angle of about 45 degrees when it poised on the 2 first pairs and stretched out the last pair free. Both *culex* and *anopheles* frequently sit with the last pair of legs lifted away from the support. But while the legs of *Anopheles claviger* stretch out with the tarsi pointing downwards, those of the various species of *culex* which came under their observation presented the tarsi curled upwards in a very characteristic manner. Lately, having brought up a number of *Anopheles pseudopictus* from larvae, the authors observed that in this species of anopheles the body forms a much wider angle with the surface of support. The angle is so wide at times that one might almost be justified in saying that the insect holds its body perpendicular to the wall. It is evident, therefore, that the observations made by Ross and

Austin in Sierra Leone were quite correct, but that unfortunately these 2 authors erred in extending to the whole genus a character which is peculiar to a few species which they had observed only in *Anopheles costalis*. [J.M.S.]

6.—Campbell reports the case of a girl of 18, who was suffering from **pulmonary tuberculosis**. The morning temperature was 101.6°, the evening, 102°. During the first week of residence, when the only antipyretic measure employed was cold sponging of the whole body 2 or 3 times daily, the average morning temperature was 101.2°, the afternoon record 102.4°, and the evening average 102°. During the ensuing 3 weeks, quinin salicylate, 2 grains, and phenacetin, 5 grains, were administered at 10 A.M. and 3 P.M., to keep the pyrexia within moderate limits and allow the patient to take a proper amount of nourishment with comfort, the average evening record then was 100.8°, including one register of 101.4°. A day or 2 before the commencement of the serum treatment the antipyretic powders were discontinued, leaving the evening register running at 102°. Ten cc. of the **anti-streptococcus serum** was injected subcutaneously in the anterior abdominal wall. This apparently caused an exacerbation of the evening temperature to 103.4°. Then 4 days elapsed and during this time the average evening temperature was 102.5°. At the end of this period 10 cc. were injected, giving rise to an evening record of 103.4°, as on the previous occasion. Then a day's intermission was allowed, as the patient complained of tenderness at the site of injection. During the ensuing 7 days the administration was continued at 11 A.M. each day, and on one occasion only the injection was repeated tentatively in the evening. In all, 10 injections were given, and during this period the average morning temperature was practically 101°, and the evening average 103.8°, although cold sponging of the body was carried out 3 times daily. With regard to the effect of the serum, it cannot be said that it has proved beneficial; indeed, judging from the temperature records of the first week of residence, the treatment has apparently caused a slight increase in the pyrexia, without having much effect on the pulse and respiration-rates. All that can be deduced from this trial is that if the marked habitual evening exacerbation of temperature in cases of pulmonary tuberculosis is really due to the action of pyrogenic organisms, the antitoxin treatment is apparently of little value. [J.M.S.]

6.—Laurent has devised a **trocar and canula** for exploration in cases of supposed hepatic abscess. It is flat (oval on section) and consequently penetrates more readily between the ribs than the ordinary circular form. It is one inch longer than the ordinary trocar and canula of Dieulafoy. It is also grooved on either side, which grooves are valuable directors insuring safety, precision, and rapidity of subsequent operations. [G.B.W.]

7.—Clark reports a case of **columnar cell carcinoma**, occurring in the testicle of a child 10 weeks old. [G.B.W.]

8.—Stanley Boyd has been able to obtain more or less full details in 41 cases of **oophorectomy in cancer of the breast**. The cases are in no way selected, but include all which the surgeons to whom he is indebted for them, had done to a certain date. He knows the results of 13 other cases, making a total of 54. Of these, 19 (35%) were more or less markedly benefited by the oophorectomy, and 34 were not at all or only doubtfully benefited, and 1 died of exhaustion. Of the 46 cases most accurately described there were 17 (37%) in which there was a marked decrease, often amounting to disappearance of superficial disease. These statistics seem to prove that atrophy of cancer masses after oophorectomy is no accidental occurrence, as some would have us believe, and any one who has seen a successful case will decline to allow that the result is due to chance. In regard to the length of time the improvement lasts Boyd remarks that a year or more of useful life seems often to have been gained, and that there is reason to think that progress of disease is sometimes delayed when it is not arrested. He has never given thyroid extract until satisfied that oophorectomy was failing in its effect and then it was without obvious benefit. So far as Boyd has observed, cancers other than mammary are not benefited by oophorectomy; even uterine cancer is not, though atrophy of the uterus follows more quickly and certainly upon oophorectomy than does atrophy of the breasts. There would seem to be differences between cancers not hitherto suspected. Stranger still it is that all mammary cancers are not affected by oophorectomy; either

mammary cancers or the ovaries differ in the different cases. His theory is that certain ovaries, probably by pathologic variation in their internal secretion, favor the growth of cancer by action either upon the growth or upon the tissues; the removal of such ovaries alone will be of benefit, but he has discovered no clue to their recognition, for the ovaries removed have usually been normal to the eye. He thinks that oophorectomy should be offered in cases other than the very acute, in women over 40, with no visceral or bony lesions, in fair condition, and before the menopause. In extensive primary cases and recurrences it seems advisable to remove what is possible of the disease; but healing should be attained, lest the oophorectomy fail in its object and malignant ulceration be started. The surgeon must decide what it is right to do in each case, and the patient or the patient's friends should understand the experimental nature of the treatment. Boyd also refers to the fact that arms so heavy with edema as to be burdensome are sometimes amputated to the great relief of the patient; and he mentions 2 cases thus treated, 1 of which was thus enabled again to busy herself with her home and children, whereas before she could scarcely get about. He thinks, therefore, that if a patient in a fair condition, who is suffering severely from the weight of a swollen arm, desires relief at the cost of a high amputation, it should not be withheld. [w.k.]

9.—Herman adds 2 more cases of **mammary cancer treated by oophorectomy and thyroid extract** to the 2 previously reported. Of these the one operated on in 1897 is still entirely free from cancer, and the others were all greatly benefited. He believes that the favorable result was not due to oophorectomy alone, but that the thyroid extract contributed to the good results. The first thing is, if possible, to define the cases in which benefit may be expected from the combination of the 2 methods of treatment, and when this has been done, then there will be time to discover how much is due to oophorectomy and how much to the thyroid. [w.k.]

12.—Griffith reports some **observations upon the structure of the knee**, namely the internal lateral ligament and the internal semilunar cartilage, based upon clinical data and upon experiments on the knee-joints removed after death. He found that bending inwards of the knee-joint is prevented by internal lateral ligament in the extended position and by crucial ligaments in the flexed position. It therefore follows, that if there is a strain thrown on the one side, resistance is offered by the internal lateral ligament when the joint is extended, and by crucial ligaments when it is flexed. In his experience, this internal lateral ligament is the most frequently damaged structure in the knee-joint, as the knee is not only bent inwards to a more or less degree owing to the obliquity of the femur inwards and the tibia outwards, but it is also subjected to severe strain whenever the knee is abducted and the foot planted on the ground, as in boxing, tennis playing, etc. Overstretching or rupture of this ligament may be recognized first by locating the exact spot of tenderness, which is usually at one or the other end of the ligament, and secondly by testing whether there is any lateral movement of the joint in the extended or somewhat extended position. There is generally associated, tearing of the capsule and synovial membrane, hence a more or less effusion in the joint cavity is always present. The severe symptoms clear up in from 2 to 6 weeks, but the patient may suffer from what he terms "a weak knee," for months or even years. Griffith has devised an apparatus which affords absolute support to the injured structure, consisting of 2 flat bars of steel, about an inch in width, fixed together by a free hinged joint which lies horizontally at the middle of the back of the knee. These bars are split longitudinally into equal halves, and these halves gradually diverge so as to almost encircle the limb. Pads and straps are applied to the anterior ends of the bar. Before a displacement of the internal semilunar cartilage can take place an accident which is frequent in athletes, it is necessary that the internal lateral ligaments be rendered non-effective either by the overstretching of its fibers or by rupture partial or complete. After rupture of the internal lateral ligament, the articular surface may be separated for $\frac{1}{2}$ inch from each other, making a space sufficiently large to allow the passage of the cartilage in between the 2 bones. Griffith suggests that instead of adopting the usual procedure of full flexion followed by sudden extension of the joint, for the purpose of reducing displaced internal semilunar cartilage, the surgeon should

rather try lateral flexion to relieve the cartilage from pressure, for as soon as this occurs, it is most probable that the cartilage will then with its own elasticity spring back to its proper place. [G.B.W.]

13.—Burghard reports 3 cases in which the **superior cervical ganglion of the sympathetic was removed**. The constant symptoms observed following this operation were ptosis, severe pains in the head on the side operated upon, congestion of the vessels of the face, and contraction of the pupil. The headache and congestion of the face varied both in degree and duration. Among the variable symptoms may be mentioned the decrease of intraocular tension and the presence of enophthalmos or the reverse. [G.B.W.]

14.—Lennander reports 3 cases in which, by **plastic operation**, he restored the proper function of the anus. In the first case the incontinence followed phlegmonous inflammation, destroyed the sphincter ani and part of the rectum. In the second case the incontinence was due to extirpation of a tubercular prostate and urethra; and in the third case the incontinence arose through the removal of a rectal carcinoma. The operation consisted briefly in the following steps: An incision is made over the lower part of the sacrum and coccyx and continued in horseshoe-shape around the ischrorectal region. The posterior part of the levator ani and the anterior part of the coccygeus muscles are opened up. The levator ani is completely separated from the coccyx and coccygeus muscle, care being taken to avoid the nerve supplying the levator ani. This opening in the pelvic diaphragm should be filled up by the medium part of the glutei maximi. These fibers are loosened from the sciatic ligament and the sacrum and coccyx; their portions of the levator ani springing from the coccyx and coccygeus muscle are brought forward and fixed to the posterior surface rectum in such a way that they will brace the rectum on either side. The glutei muscles previously removed from their origin are now stitched back in the middle line anteriorly to the levator ani, and the skin at the anus; and posteriorly with the periosteum upon the sides of the coccyx. These united muscles sink deeply between the point of the coccyx and anus and form a horizontal foundation for the pelvis, and at the same time embrace the anal portion of the rectum posteriorly and anteriorly. All 3 of the patients were much benefited by the operation. [G.B.W.]

15.—Clarke advises, in **operating on the prostate**, that the operation be done at 2 sittings. At the first the bladder is opened suprapubically and a couple of stitches passed through the bladder wall, one on either side, and a good-sized tube left in the suprapubic opening to prevent so much contraction that the surgeon would not be able to pass his finger into the bladder for examination. The drainage of the bladder thus established allows the patient to rapidly improve in health, and in a week or ten days he is ready for the second part of the operation. This time an incision is made in the perineum as for lateral lithotomy, until the prostate is reached. The finger of the left hand is then introduced into the suprapubic opening, and the prostate pushed down towards the perineum, which procedure greatly aids the removal of the gland itself. The hemorrhage in all the cases reported was insignificant, this being attributed to the subsidence of the congestion around the prostate and the base of the bladder, occurring between the 2 operations. [G.B.W.]

16.—Phelps concludes his article on the open operation for **tallipes equinovarus** briefly as follows: All feet at any age after the fourth month with shortened skin and ligaments, should be operated on by open incision. This is much better than prolonged mechanical treatment. The operation is not completed until the foot is placed in the supercorrected position, flexed upon the leg and the heel prominent so that it strikes the ground in walking before the anterior segment of the foot does. Clubfoot shoes should be discarded for massage and manipulation, accompanied with fixation of the foot in the supercorrected position by a plaster-of-paris shoe or adhesive plaster. Treatment begins immediately after the operation is completed. Osteoclasis should be performed in all cases of inward twist of the tibia, or a relapse may be looked for. Bone operations should never be performed primarily. Tendons and ligaments should be cut and not stretched. No case is cured until the heel strikes the ground first in walking. Open incision should never be performed unless the skin resists and will

not stretch sufficient to allow the supercorrection and the proper unfolding of the foot. The weight of the body falling upon any clubshoe or brace nullifies the action of the apparatus. [G.B.W.]

3.—Morgan discusses the **recent advances** which have been made in **surgery**, mentioning, among other things, the removal of tumors of the liver, the suture of wounds of the heart, operation for perforated gastric ulcer, the surgery of the brain, the use of the x rays, etc., without mentioning anything especially new. [M.B.T.]

4.—Mackenzie summarizes **31 cases of diphtheria** that he treated with **antitoxin**. He divides the cases into 7 groups: 1. Three cases of laryngeal diphtheria extending to the pharynx. 2. Six cases of pharyngeal diphtheria gradually extending to the larynx. 3. Three cases of laryngeal diphtheria confined to the larynx. 4. Nine cases of pharyngeal diphtheria confined to the soft palate, pharynx, and posterior nares. 5. Six cases of post-scarlatinal diphtheria. 6. Three cases in which serum was given for diagnostic purposes. 7. Two cases of diphtheria of the conjunctiva. [J.M.S.]

6.—Warden reports 18 consecutive cases of **abdominal hysterectomy** performed by Doyen, of Paris, with uniformly favorable results. Doyen's technic is very simple and the resulting mortality very small, from 2 to 4%. The technic comprises 7 steps, as follows: (1) Abdomen is opened and the tumor drawn out above the pubes; (2) perforation of Douglas' pouch and seizure of the cervix; (3) isolation of the cervix; (4) removal of the uterus; (5) arrest of hemorrhage; (6) closure of the pelvic peritoneum; (7) closure of the abdomen. Warden gives interesting remarks on special maneuvers. 1. The broad ligaments. Frequently the broad ligaments are unduly short owing to their attachment high up on the lateral parts of the tumor, and it is difficult to get the latter elevated well out of the pelvis. These tight bands, as it were, of the broad ligaments are at once felt by the index finger and may be caught either by the assistant or with long curved elastic forceps and cut through close to the uterus. It is rarely necessary to apply pressure-forceps to the uterine surface. If necessary the left broad ligament is similarly treated. 2. Hemorrhage from the uterine artery during the isolation of the cervix uteri. This usually occurs while the cervix is being drawn up with the tenaculum, but the surgeon is prepared for it, and it is as easy to catch it with the pressure-forceps as to catch an artery of similar caliber, say, in an amputation of the breast. As the patient is in the Trendelenburg position and is more or less congested it is frequently of use to proceed with the removal of the tumor and then return to the ligation of the 2 uterine arteries which have served the purpose of a venesection. 3. Difficulty in reaching Douglas' pouch on account of adhesions or a posterior subperitoneal fibroid blocking the pelvis. Doyen remarked upon this difficulty in 1892 and showed how slight were the changes which it was necessary to introduce into

the technic. The tumor is drawn up as high as possible, any adhesions are separated, and if there are multiple posterior fibromas present, the peritoneum and uterine tissue are incised and these fibroids easily enucleated with the fingers or the screw. If the posterior culdesac remains inaccessible the forceps in the vagina are simply pushed toward the right broad ligament, and the right lateral vaginal culdesac is perforated as close as possible to the insertion into the cervix of the lower edge of the right broad ligament and the operation is proceeded with as in more ordinary conditions. 4. Isolation of the cervix from the vagina before the abdomen has been opened. This is a maneuver that considerably facilitates the operation, especially to those undertaking it for the first time. It is well, at any rate, during the preparation and toilet of the vulva and vagina, to examine carefully the exact position and relations of the cervix. The higher it is and the more difficult of access by the vagina, the easier it will be to reach it from the abdomen. The lower and more normal it is the easier will be the preliminary circular incision of the mucous membrane per vaginam. Undoubtedly the most delicate step in the operation is the section of the lateral attachments of the cervix and of the mucous membrane of the posterior vaginal culdesac, and when this is done as a preliminary step by the vagina the extirpation of the uterus by the abdomen is of the greatest simplicity. 5. Drainage. Though not habitual it is sometimes well to drain Douglas' pouch, either after an exceptionally laborious operation or when the vaginoperitoneal wound has been plugged and not sutured. The best method is by a glass-drain introduced from the most dependent part of Douglas' pouch into the vagina and covered externally by a small pouch of thin rubber or skin to collect aseptically any fluid that may thus drain. 6. After-treatment. The patient is well purged on the second day, and sometimes on the first day, after the operation. If the temperature rises ice chopped in small pieces and placed in bladders is laid over the abdomen. He has yet to find the patient who will not find this soothing and comfortable. These are the 2 details in which the after-treatment differs from that followed in all laparotomies. [W.K.]

7.—Dodd reports **bilateral resection of the superior cervical ganglion of the sympathetic** for chronic glaucoma in a woman of 62, who had been under treatment for 14 years. As yet, not sufficient time has elapsed to make it possible to form a definite opinion as to the success of the operation. He considers the operation a severe and dangerous one because of the proximity of great vessels and nerves of the neck. It requires operative experience and great care for successful performance. If the operation does prove permanently satisfactory, arresting glaucoma, preserving the vision and relieving pain, he considers it justifiable. [M.B.T.]

9.—Lewtas reports 2 cases of **arteriovenous aneurysm** caused by the wounds of Mauser bullets in the South African campaign. In one case the aneurysm was located between the popliteal space and artery. The popliteal vein was tied above and below the aneurysm and a typical ligation of the artery was performed; good recovery followed. In a second case the aneurysm was at the upper end of Hunter's canal. The femoral artery was ligated just above the communication with the vein and a good recovery followed. He considers the practice which has existed of tying both artery and vein above and below the aneurysm and then dissecting out the sac, unnecessarily elaborate and severe. [M.B.T.]

10.—A case of fracture of the humerus with division of the **musculospiral nerve** by a Mauser bullet is reported. About 3 months after the injury, operation was undertaken. The ends of the nerve were dissected out of the cicatrix, freshened and sutured with catgut. About $\frac{1}{2}$ inch of the nerve had been destroyed, and on suturing it could be brought together within about $\frac{1}{2}$ inch. Two and a half months after the operation sensation was completely restored. All muscles supplied by the musculospiral nerve responded to the galvanic current; there was considerable increase in power in the extensors of the thumb, but wrist-drop persisted. In a second case, aneurysmal varix of the femoral artery and vein was caused by a Mauser bullet wound. The femoral artery was ligated about $\frac{1}{2}$ inch above and below the wound in the vessels, and excellent recovery resulted. [M.B.T.]

2.—Moore calls attention to some important features in the **physical examination of cardiac disease**. The notes should always state the time, quality, place of maximum intensity, and distribution of the murmur. In addition, all accessory facts, particularly the pulse, should be carefully considered. If the murmur is faint it can often be made more intense if the patient is allowed to inhale a capsule of amyl nitrite. When hypertrophy has been determined it is necessary to find its cause. It is not always possible to distinguish it from mere dilation. Among the interesting facts to which he calls attention may be mentioned the following: If the apex beat is in the sixth interspace in the nipple line, the heart may be twice its normal weight; the thrill of aortic stenosis may be felt at the apex and the base, and occasionally only at the apex, a condition possibly to be explained by the fact that the aortic cusp nearest the mitral leaflets is the one chiefly diseased. The murmurs of aortic lesion of either kind are sometimes far more distinct at the apex than at the base. Any systolic murmur distinct at the apex can probably be heard at the angle of the left scapula, but presystolic murmurs are never heard in the back. In cases of malformation of the pulmonary valves, there is a systolic murmur loudest at the left base, whilst the pulse is normal in all respects. In cases of mitral disease developed early in life, the differential diagnosis from congenital pulmonary stenosis with defect of the septum is difficult. In the latter, however, the pulse is normal, but the child does not develop as well. Pericarditis is a common complication of juvenile valvulitis. All cases of rheumatic fever in childhood should be treated as if they were cases of acute endocarditis. [J.S.]

3.—Three cases of **gastrotomy for hematemesis** are reported. A woman of 42 was admitted to the hospital suffering from recurrent hematemesis. Her first attack was 6 years previously and it has been followed by other attacks at intervals of about six months. The vomiting came on soon after eating, the epigastrium was tender, and there was a burning sensation in the stomach. The woman was not particularly anemic. She improved considerably under medical treatment, but as soon as her diet was increased the vomiting recommenced and the stools became black. The abdomen was opened in the middle line above the umbilicus; the stomach was drawn into the wound and sponges packed about. It was opened by a vertical incision on the anterior surface. The contents were sponged out and the mucous membrane was examined systematically. Two small superficial ulcers were found on the posterior wall nearer the cardiac than the pyloric end. They were triangular in shape with sharply cut edges. Silk ligatures were passed in 2 directions underneath these ulcers with curved needles and tied so as to strangulate the bases. The stomach wound was closed by double silk sutures and the abdominal wound sutured with silkwormgut. Recovery was uneventful except that vomiting persisted for the first 10 days. It then ceased entirely and the woman left the hospital free from pain and sickness, taking ordinary diet. In the second case a woman

of 34 had vomited a half pint of blood 4 days previous to entrance to the hospital. Hemorrhage recurred 4 times, twice on one day, and her stools were black. There was no history of dyspepsia or vomiting, but there had been a certain amount of pain. The abdomen was not tender, the patient looked anemic and her pulse was 132. A similar operation to that just described was performed. A small bleeding point was found on the posterior wall near the pylorus. Owing to the great loss of blood before operation, convalescence was slow, but the patient rallied and left the hospital 4 weeks after the operation, taking ordinary diet. In a third case a man of 42 had suffered from dyspepsia 5 years previously, from which he recovered. He had remained well until 7 months before admission when his old symptoms returned with hematemesis and melena. There was considerable pain and tenderness in the epigastrium. Celiotomy was performed for suspected malignant growth. Nothing was found and the abdomen was closed. On recovering from the anesthetic the patient began to vomit blood and continued through the night. The following day the abdomen was reopened. The stomach was incised and a large irregular surface was found at the cardiac end, from which blood was pouring freely. An unsuccessful attempt was made to ligate the tissues of the base of the ulcer by silk sutures. The hand was then introduced into the peritoneal cavity, the ulcerated portion of the stomach-wall was invaginated and the silk suture was tied tightly around the base of the invaginated cone. This controlled the bleeding at once. Three Lembert sutures were inserted across the puckered spot on a serous surface and the incisions in the stomach and in the abdominal wall were closed. There was no sign of fresh hemorrhage and everything went well for 15 days, when the patient vomited again. He soon began to improve rapidly, however, and left the hospital perfectly well. Two points are considered of special importance with regard to treatment of gastric hemorrhage; the finding of the ulcer and the method of dealing with it. The most satisfactory way is to inspect the entire mucous membrane through an incision in the anterior wall. No one method of treating the ulcer is available for all cases, but excision is considered the ideal method. [M.B.T.]

4.—Fermi and Tonisini record their experiments upon the **transmissibility of malaria** in the convict island of Asinara. On this island there were 11 malarial localities, in 6 of which the types of fever were severe. Three methods were employed to destroy the mosquitoes: first, covering the surfaces of the lakes and ponds with petroleum and cleansing thoroughly the drinking tanks; second, destruction of the adult mosquitoes by a mixture of powers, or by chlorine gas; and finally the exclusion of the mosquito from the dormitories. As a result of these measures, during a period of 9 months in the malarial season, no cases occurred on the island, the 9 in the hospital having all been imported. [J.S.]

5.—Russell is unable to find evidence of any kind in favor of the belief that **oblique inguinal hernia** ever occurs at any age independently of the presence of congenital sac. He believes that there is no such thing as acquired inguinal hernia. Oblique inguinal hernia in childhood is invariably associated with a congenital sac. Children may possess the sac but remain free from hernial descent throughout life or up to any period of life, but children possessing such a sac are predisposed to hernia throughout life. All cases of oblique inguinal hernia occurring at any time during the course of life occur in people who are possessors of the congenital sac and those who have never possessed congenital sac or in whom the sac has been efficiently removed can never have hernia. He considers the use of trusses in children bad surgery and the removal of the sac the only good surgery, and advocates routine operation in children. Simple removal of the sac is all that is considered necessary for permanent cure. [M.B.T.]

6.—Laslett reports the results of **saline infusion in diphtheria**. Six cases were treated in the late stage, and all died; life, however, appeared to have been prolonged. In the acute stage, 15 cases were treated. From 10 to 15 oz. were injected into the loose skin below and outside the right breast. The immediate effects were very satisfactory, the children being soothed, and often falling asleep. All cases were also treated by large doses of antitoxin. Seven died, and 8 recovered. The cases were those of the severe type in which cardiac complications appeared probable. [J.S.]

7.—Walton reports 2 cases, 1 of puerperal sepsis, another of ulcerated sore throat, in which antistreptococcus serum was used with satisfactory result. [S.]

8.—A case of **anthrax** over the sternomastoid is reported occurring in a man whose business involved handling hides. The pustule was excised $\frac{3}{4}$ inch wide of the growth and cauterized with pure carbolic acid. Very few bacilli were found on bacteriologic examination, but these resembled anthrax. Recovery followed. [M.B.T.]

9.—A woman of 57 overbalanced while standing on a chair and was thrown to the ground suddenly, and forcibly flexed her left foot. There was pain up the back of the left leg, and inability to extend the ankle following the accident. The tendo-Achillis was felt ending in a hard movable mass 5 inches from the sole of the foot and between the mass and the os calcis was a considerable depression. The fragments could not be approximated. They were cut down upon and retained by a silver wire suture, and at the end of 2 months the woman could walk quite well. [M.B.T.]

11.—A man of 24 had had an **hydatid cyst** of the liver incised and drained on 2 occasions 11 years previously and one year later. He came to the hospital with physical signs indicating a large collection of fluid in the right chest. Exploratory puncture was made. No hooklets were found in the aspirated fluid. This gave some relief, but a few days later the patient suddenly coughed up offensive smelling purulent greenish-yellow fluid. A portion of the tenth right rib was excised in the axillary line. A large quantity of foul fluid and a number of hydatid daughter cysts of various sizes were removed. After this operation the patient improved in some respects, but his cough and expectoration became more troublesome, and 2 weeks later celiotomy was performed and the region of the liver explored. It was found adherent to the abdominal wall, but otherwise apparently normal. A swelling the size of an orange was palpated in the left iliac fossa and incised. The results of this operation were also unsatisfactory and a number of punctures were made to locate the troublesome remaining cyst which was eventually found and evacuated. Gradual healing resulted and the patient left the hospital feeling quite well. [M.B.T.]

New York Medical Journal.

October 27, 1900. [Vol. lxxii, No. 17.]

1. Supplementary Report on a Recurrent Tonsillar Tumor. R. P. LINCOLN.
2. "Thimbles" for Massage and Stripping of the Seminal Vesicles. J. RILUS EASTMAN.
3. Fractures of the Nose. THOMAS AMORY DEBLOIS.
4. A Case of Total Eventration. CHARLES G. SCHMIDT.
5. Disturbances of Gastric Motility and their Significance. ANDREW MACFARLANE.
6. The Suture and the Value of Dry Sterilized Catgut. J. H. CARSTENS.
7. The Management of Normal Labor, Including the Use of the Forceps. AUSTIN FLINT.
8. Effects on Digestion of Food Prepared by the Use of an Alum Baking Powder. E. E. SMITH.

1.—Lincoln reports a case of a **recurrent tonsillar tumor**. At the first removal the growth was examined and the tonsil was supposed to be syphilitic and the case was treated with potassium iodid, but within a year following the operation the growth had attained its former size, and when examined was found to occupy half the pharyngeal space. The second operation consisted in removing the whole mass by enucleation under general anesthesia. Eighteen months later there was no symptom of return. Microscopic examination of the specimen obtained at the second operation seemed to prove that the process was one of simple hyperplastic inflammation. [O.B.W.]

2.—Eastman says that the main difficulty in the **massage of the seminal vesicles** is that the finger is unable to reach above the lower half of the vesicle in even the most favorable cases, and as the disease is by no means limited to this portion of the organ, the maneuver can readily stand improvement. This he proposes to do by the use of a **thimble** made to fit on the end of the first finger, which adds the proper length. The end of the thimble is made to represent the tip of the finger when slightly bent, and the shank of the

instrument is a little curved. The instrument is made of nickel-plated brass and should be about 3 inches in length, which adds about $1\frac{1}{4}$ inches to the finger. The massaging with the thimble should be done only after a careful examination has been made with the naked finger to determine the true state of affairs. [O.B.W.]

3.—De Blois says that in most cases of **broken nose** there is really no fracture at all, but rather a dislocation of the nasal bones at their internal borders from the nasal processes of the superior maxillaries. The most important part in treatment is in reduction of the dislocation, and which, unless ether is used, should be attempted only after prolonged and frequent applications of cocain. In many cases apparatus for holding the nose in position can be dispensed with, but if the septum bulges, or the nasal bones show a tendency to slip, an internal splint should be used, occasionally combined with the use of external splint. He reports 5 cases. [G.B.W.]

4.—Schmidt reports a case of **congenital total splanchnectopia**. The viscera were covered with only peritoneum and the child died from peritonitis on the fourth day after birth. [G.B.W.]

5.—According to Macfarlane the most reliable sign of motor insufficiency is the presence of food in the stomach when that organ should be empty. Having determined gastric insufficiency by the dilation of the stomach and the retention of food, the question arises, What is its nature? Is it myasthenic, due to a primary muscular weakness, or stenotic, the result of a mechanical obstruction at the pylorus? When the condition is purely myasthenic, the pylorus is normal, but the muscles are thin, atrophic, and show fatty or colloid degeneration. When there is a mechanical obstruction, a stenosis at or near the pylorus is present, and the muscles at first hypertrophy, then later undergo atrophic changes. The myasthenic dilation is commonly developed from a simple atony, and the most important cause is a chronic hypersecretion which induces dilation by the prolonged and incomplete digestion of the starches and the accompanying spasm of the pylorus inducing retention. Eleven cases of gastric disease are briefly reported in order to emphasize the importance of motor disturbances; 3 are cases of carcinoma, one involving the pylorus, 2 affecting the lesser curvature; 3 are cases of pyloric stenosis after ulcer; 4 are cases of gastroneuroses; and one is a case of perigastritis with pyloric stenosis due to carcinoma. [J.M.S.]

6.—Carstens prepares **catgut** for use in the abdomen in the following manner. The fat is removed from the catgut with ether and the gut cut into strips 18 or 20 inches long. Three of these strips are wrapped in fine tissue paper, and are then placed in small envelopes put in a sterilizer and subjected to a dry heat of 300° F. for 3 hours. The heat is shut off and the apparatus allowed to cool. In from 12 to 18 hours later, the sutures are again subjected to a heat of 300° F. He says that this gives a pure sterile animal fiber which is ideal for intraabdominal work. [O.B.W.]

7.—The points made by Flint in regard to the **management of normal labor** are briefly as follows: 1. The importance of making a diagnosis and a complete physical examination about 1 month before the onset of labor. This not only will give a great deal of information which may be utilized during the labor, but it affords ample time in which premature labor can be induced if there is any abnormality. 2. Infrequent examinations during labor; if the delivery of women could be regarded as a surgical operation, requiring as full and complete antiseptic details as other surgical procedures, we could confidently expect nonfebrile convalescence. The fact that sterilization of the external genitals, the thighs, and the lower portion of the abdomen is sufficient, deserves mention. An antepartum douche is not only unnecessary, but it is actually harmful, as has been shown by Leopold and others. The use of gloves has not been satisfactory. 3. The use of anesthetics should be more general in private practice. Ether possesses many advantages over chloroform, and should be used, as a rule, when the pains are of moderate intensity. We have not had enough experience with the new method of spinal anesthesia to justify its use in more than an experimental way; and if added experience shows freedom from complications, we shall have at our command a method that is nearly ideal. 4. In the hands of the general practitioner, a low forceps operation should be performed with greater frequency. It is easy of execution,

is devoid of danger, saves unnecessary suffering on the part of the patient, and often actually enables us to preserve the perineal floor intact. On the other hand, however, median operations, within the cervical canal, and high operations should be done only for some special indication. 5. Non-febrile convalescence and freedom from local discomfort in cases in which the parturient canal is intact; it is of the greatest importance in the management of normal cases to acquire skill in so guiding the passage of the head and shoulders over the perineum that the risk of even a slight laceration may be reduced to a minimum. In addition to the danger of a mild puerperal fever, lacerations have a tendency to interfere with the involution of the vagina and uterus, and they predispose to many conditions requiring treatment by a gynecologist. Too many obstetricians are careless in this respect, relying upon the usually good results of an immediate repair. [W.K.]

8.—Smith has studied the effects on digestion of food prepared by the use of an alum baking powder. He concludes that the evidence of his experiments is that food prepared by the use of a so-called alum baking powder does not interfere with secretion in the stomach; and, even when it makes up the major part of the diet, it is utilized by the body in the same way and to the same extent as an acceptable control diet. The investigation does not reveal any reason for believing such food at all injurious or unwholesome. [J.M.S.]

November 3, 1900. [Vol. lxii, No. 18.]

1. An Operation for Laceration of the Perineum; Failure of Medullary Narcosis. HERMAN J. BOLDT.
2. Fulminating Appendicitis. CHARLES A. WHEATON.
3. The Modern Cesarean Section. An Ideal Method of Treatment for Placenta Prævia. A. PALMER DUDLEY.
4. A Southern Health Resort: Climatic Advantages of Asheville, N. C., as a Temporary Residence for Tuberculous Patients. B. T. WHITMORE.
5. A Case of Paralysis of the Recurrent Laryngeal Nerve; Recovery. JOHN F. CULP.
6. Supposed Glioma of the Retina; Enucleation; No Return in Twelve Years. DAVID WEBSTER.
7. A Case of Sudden Death, Probably Due to Pulmonary Embolism. J. SHELTON HORSLEY.

1.—Boldt, after stating that he had recently two failures in the attempt to use **medullary narcosis** in surgery, in the first of which no analgesia was produced at all, and in the second it extended only to the thighs, reports in detail a third case in his own clinic, in which the cocaine injection was a total failure, and he had to resort to general anesthesia before operating for laceration of the perineum. From his own experiments with cocaine injections on animals, he thinks great care should be used. The symptoms observed in these experiments corresponded to those observed in the human subject, only they were greatly intensified, much larger doses being used. The action on the respiratory center always became manifest first. The effect upon locomotion was seen to be dragging of the hind extremities, as though they were paralyzed, which sometimes was noticed almost immediately after the injection was given. The postmortem findings were of the greatest interest in the central nervous system. The vessels of the pia of the brain and spinal cord were intensely congested, and there were minute extravasations of blood throughout the brain. The gray substance was distended with blood. The numerous convulsions, which were present when fatal doses of the alkaloid were given, may account for the overdistention of the bloodvessels in the central nervous system. Such intense symptoms being present when cocaine was injected in other parts of the body, we should be doubly careful when it is injected into the spinal canal. [W.K.]

2.—**Fulminating appendicitis** is a condition which comes rather under the category of surgery than of a general medicine, and Wheaton says that the sooner this is recognized, the better for the patients suffering from this malady. In all probability less than 1% of the cases of this character would end in recovery if it were not for surgical intervention. In operating in these cases, it is a very good rule that if the patient is not worse after 48 hours of observation, let him alone; let him get well. But, it is also very important that the patient should be carefully watched by a surgeon during

these 48 hours, and if any serious symptoms developed, operation should at once be proceeded with. There is one symptom in connection with peritonitis which does not appear in textbooks, and which Wheaton believed occurs in almost all cases, and is an unfailing sign of general abdominal suppuration; this is an apparent vasomotor paralysis which brings about a cyanosis of the trunk, notably of the abdominal region. High temperature and high pulse, associated with local pain and rigidity in the region of McBurney's point, are strong presumptive evidence of malignancy in the attack, and if associated with the vasomotor disturbance just referred to, are practically proof positive of the condition of the perforation. The surgeon should feel it his duty to operate in all cases, no matter how desperate, unless death is actually coming on. To sum up, in every fulminating case of appendicitis, operate first and philosophize afterwards. [G.B.W.]

3.—Palmer Dudley considers the **modern cesarean section** as the **ideal method of treatment for placenta prævia**, ideal because thus the lives of both mother and child may best be saved. He endorses the conclusions of Reynolds: 1. That when the mother's vitality has been seriously lowered, by either septic infection, prolonged labor, or complicating conditions, the mortality of the cesarean section is so high that he deemed it an unjustifiable operation, and advises resort to other methods. 2. That when the mother is in good condition, uninfected, not exhausted by long labor or prolonged efforts at instrumental delivery, the cesarean section is so safe an operation that it may be resorted to unhesitatingly. Dudley considers that the physician should be able to make a certain aseptic antepartum diagnosis of the existence of a placenta prævia before hemorrhage or other untoward symptoms have appeared, and then a properly performed cesarean section is the most certain means of saving 2 lives. He considers the life of a child as good a reason for the performance of a simple abdominal operation, as the chronic backache for which such operations are daily performed. [W.K.]

4.—Whitmore's article deals with personal impressions of Asheville, N. C., and with facts obtained from conversations with the resident members of the medical profession. [J.M.S.]

5.—Culp reports the case of a lawyer, aged 36, who recovered from an attack of **paralysis of the recurrent laryngeal nerve**. [J.M.S.]

6.—A case of supposed **glioma of the retina** reported by Webster, occurred in a child 2 years old. The tumor had grown out and produced a bulge at the supranasal and anterior aspect of the globe. The patient was seen 12 years after the operation, having had no return of the tumor. [G.B.W.]

7.—Horsley reports a case of sudden death which he believed was due to **pulmonary embolism**. The patient had been operated on for vesical calculi by the suprapubic route about 15 days before. He was unable to verify his opinion by an autopsy. [J.S.M.]

Medical Record.

October 27, 1900. [Vol. 58, No. 17.]

1. Puerperal Sepsis; Its Pathology and Treatment. WILLIAM R. PRYOR.
2. Foreign Bodies in the Esophagus. GEORGE W. KING.
3. Report of Three Cases of Intestinal Obstruction Due to Meckel's Diverticula. JOHN F. ERDMANN.
4. Electric Light; Its Physiologic Action and Therapeutic Value in Tuberculosis of the Throat and Lungs. W. FREUDENTHAL.
5. The Importance of Preliminary Treatment for Intranasal Operations. CARL SEILER.
6. A Contribution to the Diagnosis of Suppurative Appendicitis. A. R. BIN.
7. Intestinal Obstruction Complicating Appendicitis, with the Report of a Case. THOMAS M. PAUL.

1.—Pryor divides **puerperal sepsis** into septic thrombosis and pelvic lymphangitis. The most rapidly fatal cases are thrombic. In regard to treatment, he concludes that repeated irrigations do harm; curettage gives 20% mortality

and serumtherapy gives 33% mortality. He says perform rapid hysterectomy in cases of thrombosis, and in cases of true puerperal sepsis, curettage and the culdesac operation. [W.K.]

2.—While playing, a girl aged 6 years, allowed a whistle to slip into her throat. It was located by x rays and an unsuccessful attempt was made to remove it through the mouth. Esophagotomy was performed, the incision being made along the anterior border of the sternomastoid muscle. The whistle was dislodged and removed by forceps. A good recovery resulted. [M.B.T.]

3.—Three cases of intestinal obstruction by Meckel's diverticulum are reported. A feature of interest was the pronounced resemblance in all the cases to appendicitis and in 2 cases this condition really existed as a complication. In one case of but 24 hours' standing, the condition of the patient was such that the gut was simply liberated and left on the abdomen. Death resulted and at the necropsy 7 feet of intestine were found strangulated. In the other 2 cases the diverticulum was excised and the opening closed by tiers of sutures; the appendix was also removed. Uncomplicated recoveries followed in these cases. [M.B.T.]

4.—Freudenthal reviews the most important work that has been done in the **therapeutic effect of electric light**, particularly referring to Bengel's demonstration that darkness caused the motion of ciliated corpuscles to cease while sunlight set them in motion once more. He then describes a lamp (a modification of Voltolini's) which he has used in the treatment of laryngeal tuberculosis. The results which have been obtained by this method have undoubtedly been encouraging, though in some cases they were not equal to expectations. Freudenthal thinks that an improved lamp will give better results and make the treatment a very valuable one. The lamp is applied externally. [D.L.E.]

6.—Robin emphasizes the importance of a white-blood count in the diagnosis of **suppurative appendicitis**, though he points out that in some cases the advent of toxemia is so rapid that no increase of the leukocytes is present. He cites a case in which he found the discovery of hyperleukocytosis an important aid in early diagnosis. [M.B.T.]

November 3, 1900. [Vol. 58, No. 18.]

1. Modern Quarantine in Its Relations to Passengers, Crew, and Cargo. ALVAH H. DOTY.
2. Incineration vs. Earth Sinks and Chemical Disinfection. WILLIAM G. BISSELL.
3. Some Cases of Acute Appendicitis. ALEXANDER B. JOHNSON.

1.—Doty states that rules which are theoretically based upon sound scientific principles are not always found to be practically useful or necessary. For instance, it would seem from general principles that clothing worn by well persons would be a medium of infection. This he considers entirely undemonstrated and states that but one case has ever come to his attention in which the clothing actually worn by a well person caused infection. He also thinks that there has been no demonstration that **ship cargoes ever cause infection**. He makes the wise suggestion that all persons on a ship suspected of carrying infection should have their temperature taken before they are allowed to pass quarantine, and states that this procedure has been enforced at the New York station with most gratifying results. He mentions an instance in which several cases of yellow fever were discovered in this way when they would have been passed over by the usual inspection. [D.L.E.]

2.—Bissell describes an **incineration** which he has devised and which has been successfully used in destroying the excrement in camps. The Sixty-fifth regiment, N. Y. N. G., used 2 of the wagons described, each carrying 8 incinerators, destroying the excrement of over 500 men for a period of 7 days with entire success, and other favorable reports are detailed. [D.L.E.]

3.—Johnson reports the results of his experience in treating 40 cases of **acute appendicitis** during the past year and gives brief histories of the cases. The points of chief interest in his article are his views as to the treatment of general peritonitis. In several cases recovery took place in spite of extensive involvement of the peritoneum in the in-

flammatory process. These appear to demonstrate fairly well the value of abundant saline irrigation of the peritoneal cavity through a moderate incision without evisceration, in cases of widespread purulent peritonitis. The number of cases which may be described as cases of general purulent peritonitis were 8; 3 of these were fatal—a mortality of 37.5%. Several of the patients who recovered appeared at the time of operation to be in a most unfavorable condition; not only were there present the signs of severe sepsis, but the appearance of the interior of the abdomen was in several instances exceedingly unfavorable. Johnson is inclined to think that had the intestines been removed from the belly and washed and wiped, the patients would not have recovered. He considers that at the present time it is hardly necessary to mention this method of treatment in cases of purulent peritonitis except to condemn it, yet several prominent surgeons in this country are still practising it. Granting that a certain proportion of these patients recover after evisceration, yet he is inclined to think that the same good result might have been accomplished by less dangerous means. All who have tried this method must admit not only that the immediate effect of such procedures is a severe strain upon the lowered vitality of the individual, but that subsequent paresis of the bowel is a not uncommon and dangerous sequence. [M.B.T.]

Medical News.

October 27, 1900. [Vol. lxxvii, No. 17.]

1. The City and its Consumptive Poor: A Plea for a Municipal Sanatorium Outside of the Corporate Limits. ALFRED MEYER.
2. Repairing the Abdominal Wall in Ventral Hernia: A New Operation. CARL BECK.
3. A Plea for the More Frequent Avoidance of Exsection of the Ovaries in Connection with Operations upon Diseased Tubes. PHILANDER A. HARRIS.
4. The Importance of Rest in Pulmonary Tuberculosis. CARROLL E. EDSON.
5. Present Status of Interstate Reciprocity Concerning Licenses to Practise Medicine. EMIL AMBERG.

1.—Meyer believes that it is to the interest of the city to take care of the consumptive poor in **municipal sanatoriums**. In addition to the fact that this will supply to some extent the inadequacy of the present accommodation for this class of patients, it will prevent infection and promote in some cases, at least, a cure. He does not think that it would mean necessarily a great expense to the city; at present an appropriation of \$300,000 is asked for, and he believes that \$5,000,000 would be sufficient to provide the requisite facilities, and the annual cost need not exceed \$1,000,000. He assumes from the fact there are about 8,000 deaths every year in Greater New York from this disease, that there are probably 25,000 or 30,000 cases of the disease in various stages in this same area. He concludes with some statistics regarding the cases at present under hospital treatment, and urges the real economy and necessity of separate institutions. [J.S.]

2.—Beck reports a new operation for covering in defects of the abdominal cavity left after operations for appendicitis, in which wide packing had been necessary, and the thin scar resulting easily gave away and allowed the formation of a **ventral hernia**. In the case reported, Beck made use of the rectus muscle for closing in the muscular gap. An incision was carried along the inner border of the rectus, separating it from the linea alba and allowing it to be split, so that the outer fibers might be turned hinged-like over the gap which laid external to the muscles' external border. Two months later the patient was operated on for congenital inguinal hernia, and the recovery from both operations was very satisfactory. [G.H.W.]

3.—See PHILADELPHIA MEDICAL JOURNAL, Vol. V, p. 1280.

4.—Edson calls attention to the importance of **rest** in the severe stages of **pulmonary tuberculosis**. He thinks that it is always important when there is fever, and that it acts by diminishing the degree and depth of respiration, and giving more opportunity for healing in the diseased lung. He advocates placing the patient in a steamer chair in the open air for long periods, and notes that under those circum-

stances his appetite is often excellent, and that he gains in weight. [J.S.]

5.—Amberg urges a **State control** of medical colleges, believing that in this way there is the greatest likelihood of obtaining uniformity in medical education, so that it will be possible to do away with the existing barriers between the States. [J.S.]

November 3, 1900. [Vol. lxxvii, No. 18.]

1. Treatment of Puerperal Eclampsia. J. B. KILLEBREW.
2. Observations Upon the Quartan Malarial Parasite and Upon the Staining Reactions of the Tertian, Quartan and Estivo-Autumnal Parasites. CHARLES F. CRAIG.
3. Is Living Animal Tissue Capable of Neutralizing the Effects of Strychnin and Venom? An Experimental Study. S. J. MELTZER and G. LANGMANN.
4. Eye-Work in General Practice. S. W. S. TOMS.
5. Present Status of Interstate Reciprocity Concerning Licenses to Practise Medicine. EMIL AMBERG.

1.—Killebrew divides the causes of eclampsia into the predisposing, the essential, and exciting. The greatest interest is centered in the essential cause, because it is by preventing or removing that, the physician is able to prevent or cure the disease. As the phenomena characteristic of eclampsia are due to an excess of toxins in the system, which toxins are produced in the body, the most rational method would be to arrest the formation of these bodies. But as it is not known what they are or how they are formed, efforts at prevention are often unavailing. But as these poisons are undoubtedly eliminated by the excretory organs the best practical treatment is that which will dilute the toxins circulating in the blood as much as possible and at the same time increase the activity of the excretory organs. The best agent for accomplishing this is normal salt-solution. If there are strong indications that toxemia is present and that convulsions are impending, then the use of normal salt-solution is important as a prophylactic measure, giving it as a high enemata in quantities varying from 1 to 3 pints once or twice in every 24 hours. If, however, this does not prevent convulsions, or if the patient is having convulsions when first seen, more active measures must be taken. The convulsions should be controlled with inhalations of chloroform. One of the superficial veins at the elbow should be exposed and opened and the dark toxin-laden blood allowed to flow from the distal end of the divided vein, while normal salt-solution at the temperature of about 100° F. is injected into the proximal end. Ordinarily from 12 to 24 ounces of blood should be withdrawn and from 2 to 3 times that amount of salt-solution injected. Empty the uterus. Some physicians empty the uterus before giving the salt-solution, but Killebrew considers this a mistake; for the intravenous salt-solution may itself be sufficient to prevent any further convulsions. [W.K.]

2.—Craig has had the opportunity of studying 12 cases of quartan malarial infection apparently with a view to determine the differences of the plasmodium of this disease from that of the tertian and estivoautumnal forms. The chief peculiarities are as follows: In the quartan organism the pigment is motile only in the very young forms; it is always dark brown, and in the form of round granules. After the first 24 hours the outline is very distinct, and the organism appears to be stamped into the corpuscle; the amoeboid movements are slight at all times, and cease at the end of 36 hours. The corpuscle that has been invaded is somewhat shrunken and greenish in color, but rarely crenated. It resembles in general the estivoautumnal parasite more closely than the tertian. For staining, Craig prefers Romanowsky's or Chenzinsky's methods, the latter giving often very beautiful results; he also mentions Futeher's recent method in which thionin is used, and the whole process can be accomplished in less than 5 minutes. Morphologically the plasmodium, when stained, exhibits a dark ectoplasm and a pale endoplasm, really the nucleus, a nucleolus is also often present. Later it stains more homogeneously; the pigment apparently never invades the nucleus, it is found at the periphery in the younger stages, and in the center in the stages just before segmentation, in the crescents the area immediately surrounding the pigment is often paler than the other parts. [J.S.]

3.—Meltzer and Langmann have made a series of experiments with the **poison of rattlesnakes**, and with strychnia in order to determine whether the statements of von Cyzblarz and Donath are correct. These authors have maintained that animal tissues are capable of neutralizing poisons, particularly strychnin, and have attempted to prove it by injecting a lethal dose into the leg of a guineapig that had been isolated by a ligature. With rattlesnake poison Meltzer and Langmann found that a feeble dose injected into the ligated leg of the guineapig did not cause death as rapidly as when injected into the general circulation. The retardation varied from a few hours to more than a day; the local reaction was always very severe, varying approximately with the duration of the ligation. The experiments with strychnia were exceedingly interesting. Upon frogs a dose of .0001 gm. would cause tetanus several minutes later in the frog with the ligated leg than in the normal frog, otherwise the results were the same, and if larger doses were employed there was no retardation. Upon rabbits even a simple retardation as a result of the ligature could not be demonstrated. Upon guineapigs, however, the results were somewhat different; the effective minimal dose injected into an animal whose leg had been ligated produced no characteristic symptoms, or only those of an exceedingly mild nature. If after the removal of the ligature the subminimal dose were injected, characteristic convulsions were produced, showing that part of the original dose remained unaltered in the tissues, some of the strychnia was therefore neutralized. If this were due to the action of the tissues, the more tissue to which the drug was exposed the greater the amount of neutralization. Therefore injections of portions of the minimal dose into several ligated extremities should have a less effect; as a matter of fact, however, such injections invariably produced tetanus. Finally, if the dose were injected immediately after the removal of a ligature that had been kept in position for several hours, the effects are considerably retarded; the authors therefore, conclude that constriction of a limb retards the fatal outcome of snake-poison and diminishes the effect of a minimal dose of strychnia by impairing the power of absorption within the constricted leg. [J.S.]

4.—Toms calls attention to an important fact, that many cases of **nervousness and general debility** are often treated in vain, until the eyes are examined and muscular disorders corrected. He quotes a number of cases to show this, especially one case of insanity, due to eye-strain, which the attending physician had failed to recognize. [G.N.W.]

5.—Amberg continues his paper, giving the replies of the various boards of health regarding the nature of their examinations, and their willingness to practise **reciprocity in medical privileges** with the other States. He suggests that the medical societies should appoint committees to study this question, and to disseminate knowledge upon it, believing a qualified medical practitioner should be available for any patient who desires his services. [J.S.]

6. Removal of the Greater Part of the Stomach for Carcinoma; Closure of the Pyloric End; Anastomosis between Jejunum and Cardiac End; Recovery. W. A. BROOKS.

1.—In many cases of **congenital dislocation of the hip-joint** reduction has been performed apparently successfully, yet relapse has followed. Relapse is more frequent after operation without incision than after operation with incision. An important obstacle exists frequently in the fold of the capsule of the joint which is attached to the lower

part of the acetabulum and which may be called the acetabular hymen. This is often pressed in front of the entering head of the femur allowing apparent reduction but preventing complete reduction and favoring relapse. Bradford's experience led him to favor operation by open incision. He states that his results have been constantly improving during the past 10 years. He has operated upon children of ages ranging from 1 to 14 years, but most satisfactorily in children over 2 and under 7. It is not claimed that operation by incision can be permanently successful in all cases, but it is successful in many cases and it can be expected that it will be without danger to the patient and with a reasonable chance of success. During the past year Bradford has had 7 cases, 10 hips in all being reduced, first with the bloodless operation. All of these relapsed; 9 were operated upon again by radical reduction with incision; 4 remained firmly replaced as shown by x ray; 2 were firmly replaced, but as yet no x-ray photograph has been secured; one was apparently reduced; 2 relapsed after radical operation and one relapsed after bloodless operation without attempt at radical reduction. [M.B.T.]

2.—The office of coroner has probably existed for a thousand years, possibly for a longer period. Many singular customs were connected with the system. Any personal chattel, animal, or thing, forfeited to the king for pious uses, on account of its having caused the death of a human being, was termed a *deodand*. This became deservedly unpopular and the Act of 1846 did away with it. The term *felo de se* is nearly synonymous with suicide. It had, however, occasionally a more restricted significance when applied to any one who committed an unlawful malicious act, the consequence of which was his own death, as if, attempting to kill another, he ran upon his antagonist's sword, or shooting at another, the gun burst and killed himself. For many centuries it was the custom in England to bury each *felo de se* on the highway with a stake driven through his body. This ignominious form of burial was abolished in the reign of George IV, by an Act of Parliament which ordered the burial of the body of a *felo de se* within 24 hours after the inquest, between the hours of 9 and 12 at night, and without the rites of Christian burial. A condensed statement of the coroner system as it now exists throughout the United States follows. It was shown after a 3 years' experience in Massachusetts that the abolition of the jury, and the introduction of a system requiring investigations by skilled practitioners of medicine in every case of violent death, had not only wrought a marked improvement in the method of work, but had resulted in a material financial saving to the State, so that the cost was only 1½ cents per capita, or less than ½ as great as in New York, and this to over a territory of 8,000 square miles. The old-time coroner is a foe to medical progress, and it is time to "move on his works." [J.M.S.]

3.—District Attorney Harris read a paper before the Massachusetts Medicolegal Society on *autopsies and physical examinations*. In making an autopsy in a case of violent death the examiner should approach his case with mind open, unbiased and unworried by theories and opinions. He should note every normal appearance. He should also note carefully the appearances following upon his own operations. The contents of stomach, bowels, bladder, and other organs should be accurately observed. Surrounding objects ought not to go unnoticed. Very many of these things may be noticed and not reported. Above all, in a case when, by any possibility, a charge of unlawful killing may be made, judgment as to the manner of the killing ought to be suspended. The medical examiner is not a prosecutor; he has no power to commit or examine parties. His duty is to ascertain facts within a certain field, and instruct the officers of the law in regard to them. He cannot anticipate explanations or defences. If careful and thorough in his work, however, he can pass upon them when offered, and tell whether they are good. In the matter of physical examinations the expert has become a partisan. He cannot treat his case as he does his patients, disinterestedly. He is bound to one side of the case, and is always a plaintiff's or defendant's expert. The author, speaking of his relation to the medical profession, says: "I try on both sides; I have to consult your profession; and I can see no reason why, if it chances that, when trying for the plaintiff, I meet a physician whose opinion seems to me to be entitled to weight, I should not consult him when I need a man for the defence to

instruct me as to medical facts or probabilities. All I want is his best knowledge; when I get that I shape my own course. As in the case of the autopsy, the physical examination is for the purpose of gaining information, evidence; of establishing that a condition does or does not exist, and testifying accordingly. It is not intended for the purpose of enabling you to ascertain conditions, and then raise theories to account for them that have no foundations except in theory. You come to us for opinions in law, based on facts stated, and you do not want us to suppose some other facts and give opinions based on them, and you do not want us to tell you that your facts are mere imagination. I am moved to say what I have, only by my desire that our two great professions may be held in the esteem to which they are entitled." [J.M.S.]

4.—A woman of 24, while working in a steam laundry, had her left hand caught between 2 rollers. The back of the hand came in contact with a felt roller and was badly lacerated, but not burned. The palm came in contact with the heated roller, and was both badly burned and lacerated. She was treated at a hospital for 2 months, and left with a delicate cicatrix on both surfaces of the hand. This slowly contracted, producing flexion of the fingers and thumb until at the end of the year the ring and little fingers were drawn down on the palm, and the thumb was strongly flexed. The hand was practically useless and quite painful as well. The *palmar cicatrix* was wholly dissected off; the palmar tendons were not adherent. An outline of the freshened surface was made and the flap was dissected up from the left side of the abdomen. This was fastened to the palmar surface by sutures, and the hand was held in position by adhesive plaster straps. Fourteen days later the abdominal pedicle was cut, and the abdominal wound was allowed to heal by granulation. The result is considered successful. [M.B.T.]

5.—Prince's paper on *physiologic dilation and the mitral sphincter as factors in functional and organic disturbances of the heart* is an abstract and seems so important that we give it almost as it appears: "This subject is of great practical importance, not only in examinations for civil service, life insurance, etc., but for a clear understanding of diseased conditions. I used to reject many men whom I now would not think of rejecting because of this evidence of regurgitation. Sir William Broadbent has lately called attention to the great number of murmurs heard over the various cardiac orifices in candidates for civil service examination, and this, I am pleased to think, has corroborated the accuracy of my own observations, although he has not undertaken to give an explanation of the mechanism of the murmurs. He calls attention to the unnecessary rejection of candidates for civil service because of murmurs of this kind. The recognition of this principle of physiologic dilation whenever the heart is called upon to do an increased amount of work, no matter from what cause, is of the utmost importance. This dilation within normal limits may be so great that the volume of the blood thrown out at each contraction may be trebled or quadrupled. At the end of systole the heart may be larger than it was before at the end of diastole. The sphincters may be so dilated that the valves cannot close the auriculoventricular orifices and thus physiologic regurgitation may result. Normally this is observed under nervous excitement and severe physical exercise. The same law of necessity applies as much to diseased hearts as to healthy hearts and, for example, the dilation observed in aortic stenosis may be physiologic rather than pathologic. In general systemic conditions, such as the febrile diseases, anemia, Bright's disease, etc., the dilation and regurgitation are of the same sort, due either to an absolute increase of resistance or a relative increase; in the latter case because of a weakened heart working against normal resistance. Unless this is recognized there is great danger of confusing this purely physiologic condition, which probably exists in a great many such cases with serious cardiac disease and in consequence giving an unfavorable prognosis. As to the absence, notwithstanding the dilation, of murmurs in the contestants of the last Marathon race, I agree with Dr. Williams in his explanation. To this I would add the fact that the heart was not beating with the force which I think is necessary to produce murmurs. It did not seem to me the heart was beating very strongly in any of them. They were examined so long after the race that the heart had quieted down besides being weakened by

fatigue. The heart's action did not compare with the action in the men who were under the nervous stress of the civil service examination. Besides that, the absence of murmur does not so frequently denote the absence of regurgitation, as is frequently assumed. Every one admits, in principle, that you can have regurgitation without murmur, but, in practice in the consulting room the tendency is to say: 'No murmur, no regurgitation.' It is well recognized that even in organic disease, where there is mitral regurgitation, when the heart becomes weakened the murmur ceases, but when the heart recovers strength the murmur appears. In the cases of the Marathon runners I think the weakened force of the heart is a perfectly satisfactory explanation of the absence of murmurs. As a matter of fact, and this Drs. Williams and Arnold showed last year, they are fugitive, and only appear when the hearts are beating strongly. This was my experience. In most of the cases they are very fugitive and have got to be caught 'on the fly.' I feel fairly confident there was regurgitation in the Marathon runners, even in the absence of murmurs. I base this on the cyanosis present, the feeble circulation, and the condition of the kidneys, showing passive congestion, as well as on the dilation of the heart." [J.M.S.]

6.—A man of 44 was taken with epigastric pain 2 years previous to the time when first seen. About a year later he began to be troubled with attacks of vomiting and began to lose in weight. Examination of the stomach-contents showed that there was no retention of food, but HCl was absent. There was no blood or shreds of tissue. A median incision was made from the ensiform to the umbilicus and the stomach was found to be occupied by growth which extended from the pyloric end a considerable distance toward the fundus. A loop of jejunum was brought up and lateral anastomosis was established between it and the top of the fundus. Lembert sutures were used. Two ligatures were then passed around the pyloric end of the stomach and the stomach-walls were severed between them. The greater and lesser omenta were tied off and divided. The stomach walls were then cut loose to the place where the anastomosis had been made and nearly the entire organ removed. The free edges of the stomach were then united with a series of Lembert sutures. The patient made a good recovery from the operation and has gained considerably in weight. Sufficient time has not elapsed to determine the ultimate outcome of the case. [M.B.T.]

1.—La Garde gives some observations on the effects of the 7 mm. Mauser rifle bullet, drawn from a study of 1,400 wounded in the Spanish-American war. The shock on impact from the reduced caliber bullet is always less than that of the 7 caliber leaden bullet. As a rule, men fall when hit at once, and the Mauser seems to have sufficient stopping power for the ordinary purposes of war. Explosive effects were seldom witnessed. The flesh wounds generally heal rapidly and infection was seldom noticed. Out of 1,400 wounded none died of external hemorrhage nor was it necessary to ligate a vessel for alarming hemorrhage on the field. Three ligations were performed for aneurysm and in 5 cases amputation was required for gangrene from injury to bloodvessels. Injuries of the diaphyses were, as a rule, attended with but little comminution. It was rarely necessary to remove loose fragments of bone. Clean-cut perforations of joints without fracture were the usual injuries; 58% of the injuries of the head resulted fatally and 24.5% of the injuries of the thorax were fatal. It has been found, however, that of those who recovered 37% developed complications like hemothorax, pyothorax, etc. Penetrating gunshot

wounds of the abdomen were very fatal. Of 41 recorded cases 29 died. The value of x-ray diagnosis was early recognized and no attempt was made to locate projectiles except with the x-ray. Orders were given not to remove lodged projectiles except for urgent reasons. [M.B.T.]

2.—Burt reports the case of a boy, aged 11, who presented a family record of tuberculosis. A sister and 2 brothers of the patient were alive and well, except that 2 of the children had recently had a mild purpuric eruption upon the lower extremities. One year ago the patient was operated upon for enlarged glands in the neck, said to be tuberculous. On December 27, the boy began to bleed from the gums, and shortly afterwards the mother noticed a number of small hemorrhagic spots scattered over his body, but more especially upon the lower extremities. The patient was anemic; the pulse weak and rapid; the temperature 101°; blood oozed from the gums, which were not swollen. There was a purpuric eruption, moderate in extent and amount, chiefly on the legs and thighs. Both heart and lungs were normal; there was no swelling or tenderness of the joints, no edema, no pain, no soreness of the throat and no gastrointestinal disturbance. The urine contained a trace of albumin, but no sugar. Microscopic examination showed abundant hyalin and finely granular casts; a moderate number of cellular and coarsely granular casts; a few red and white blood-corpuscles, and bacteria. During the first 4 days that the patient was under observation he continued to bleed more or less from the gums, and finally from the nose, despite temporary relief from plugging the nostrils and the application of astringents. On the fifth day he bled freely from the nose, vomited considerable blood, and passed blood from the bowels, at first in the form of black stools, and then in clots of pure blood. Transfusion of a normal saline solution was performed and stimulants were administered, but in spite of treatment he was delirious by midnight. The following day his temperature ranged between 99° F. and 100° F., and his pulse between 120 and 140. He had 2 small black stools. On the seventh day he had 6 bloody stools, and vomited blood. He was in a stupor with intervals of delirium. His temperature was from 100° F. to 101° F. On the eighth day he had a small stool of blood and mucus; his pulse was weak, rapid and irregular; the delirium continued. On the ninth day his temperature ranged from 99.8° F. to 102° F., his pulse from 140 to 150, and his respirations from 30 to 40 per minute. Finally, upon the tenth day, he died. There was no autopsy. A diagnosis of **purpura hemorrhagica** was made. [J.M.S.]

4.—Theoretically, the best treatment of peptic ulcer is by complete rest of the stomach, for the longest possible time, but this cannot be obtained in every case, owing either to the patient's objections to the incidental discomforts, of which the chief is thirst, or to the intolerance of the rectum which may soon come on; yet, in an experience with a considerable number of cases requiring **rectal feeding**, during the past 3 years, intolerance has not seemed to be acquired sooner with the larger than with the smaller amounts injected, while the comfort of the patient is certainly enhanced and thirst alleviated by the larger quantity of fluid. Sears' routine method has been to give a high enema of plain water, early in the morning. This is retained by the patient, if possible for an hour, at the end of which time, if it has not come away, an enema of soap-suds is given to cleanse the rectum for the work of the day. The nutrient injection of peptonized food is then given through a half-inch soft rubber tube. The patient's buttocks are raised and an attempt is made to get the fluid beyond the sigmoid flexure. It is possible to insert a tube of this caliber, which is almost too stiff to bend up on itself within the narrow limits of the rectum, from 8 to 12 inches. The fluid is injected slowly, the tube being gradually withdrawn. Efforts at expulsion are restrained by a pad in the usual way. The enemata are repeated every 6 hours. It is not claimed that all the necessary nourishment can be given in this way, yet in one of the cases reported the improvement in the anemia and the apparent gain in weight were encouraging signs, and show that it is possible to prevent the patient at least from losing ground. [J.M.S.]

5.—Of 250 cases of disorder of the stomach which Hewes has treated during the last few years, the condition of **achlorhydria** was present as a constant condition investigated by several analyses at considerable periods of time in 15. Of these, 6 were cases of simple chronic gastritis, 4 of gastritis,

with carcinoma of the stomach, 1 achylia gastrica, and 3 in which the achlorhydria was the only abnormal objective sign. The results of the absence of hydrochloric acid in the stomach are: (1) an absence of peptic digestion; (2) an increase of bacterial fermentation in the stomach and intestine. The first aim in the treatment of this condition is the preservation or adjustment of the motor function of the stomach. The proteid diet must be in such a form and given in such a manner that it can be easily passed through the stomach; the starches with the cellulose envelop broken so that salivary digestion may occur freely in the stomach. In some cases the achlorhydria has existed for years, and it is only when the motility of the stomach becomes affected that the patients have symptoms of stomach-trouble and come for treatment. A proper regulation of the diet, with a regimen of rest after meals, and regular outdoor exercise and exercise of the abdominal muscles, with strychnin or hydrochloric acid and strychnin given internally, soon causes in these, as well as in the more numerous cases of hyperchlorhydria, a relief of symptoms, and presumably a readjustment of function. The device of supplying the hydrochloric acid for peptic digestion by the administration of the artificial acid, often useful in cases of hyperchlorhydria where the deficiency of acid is slight, cannot be utilized with success in achlorhydria, as it would be necessary to use excessive amounts of the acid. The primary treatment of cases in which the motility is affected should be the adjustment of the motility of the stomach. Where this function is intact, antiseptics destined to act in the stomach (salicylic acid, resorcin, or large quantities of hydrochloric acid given frequently throughout digestion) or in the intestine (salol) may be useful in limiting fermentation. Cases in which intestinal sepsis is suggested by the symptoms the antiseptic treatment must be applied and foods which do not easily undergo fermentation must be given. [J.M.S.]

6.—Swan has been many times impressed with the unsatisfactory results in the cases of some pulmonary invalids sent to Colorado either from the far advanced stage of their disease, or because they were landed with little or no means of support, unable to work and among strangers, or because of an erroneous idea of the sort of life they should live. The three classes of invalids spoken of, unless the conditions named are changed, would be much better off and be much happier, were they to remain at home, among their friends and associates. The outlook for patients with far advanced disease is much less favorable, and they require much more prolonged rest and careful feeding than those in earlier stages of the disease. It is not an unusual occurrence to see a patient, after 3 or 4 months' residence in Colorado, in a materially worse condition than on his arrival, and to find that he came with the belief that if he could "live out of doors," exercise, ride horseback, play golf, tennis,—do anything to keep him in the open air,—he would get well. It is a definite fact that a person coming to Colorado from a lower altitude, until he is adjusted to the change, fatigues much more easily than at home. At the same time the bracing, exhilarating air often acts as a constant nervous stimulant which spurs one on to excessive exercise until at length his physical limit is exceeded, his powers of resistance depressed to such a degree that the tubercle bacilli or other germs within him seize their opportunity, a fresh or extended infection occurs, and a partially quiescent process is fanned into activity, which may require weeks of absolute rest and careful nursing and attention before the patient can safely go about again. The writer would urge, then, 3 points. 1. Do not send patients with far advanced phthisis to Colorado unless they are able to make the change without serious fatigue, and unless they can live here in the manner they should for a prolonged period. 2. Do not send early cases, unless there are assured means for proper hygienic living for a period sufficiently long to get the patient well enough to earn, in part at least, his living, and to find employment. How long will depend upon the individual case and his progress, but, roughly speaking, 3 or 4 months at least. There are many openings for employment, but more people looking for the desirable ones. 3. Most important of all, instruct the invalid to rest and keep quiet after his arrival until some one competent to advise him considers it safe to begin to exercise, and then have his manner of life and hygiene directed from time to time, according to his progress and condition. [J.M.S.]

10.—Barbat believes that over 90% of all patients who have true appendicitis and who are not operated on have recurrences. We should operate in all cases of chronic recurrent appendicitis, if possible between attacks. In practically all patients that die after operation we find at least 48 hours between the onset of the attack and the time of operation, therefore it is reasonable to assume that if these cases had been operated upon inside of the 48 hours the patients would have been cured. As soon as a diagnosis of acute appendicitis is made he believes we should operate immediately. Pulse and temperature are not taken into consideration in making a diagnosis of appendicitis. In acute cases the diagnosis must be based on the symptoms which were manifest during the first 3 or 4 hours. [M.B.T.]

Chronic Parenchymatous Nephritis. — Billings (*Medical Standard*, November, 1900) doubts the usefulness of cupping over the loins, because the blood going to the kidney comes from the aorta and has absolutely no relation to the bloodvessels of the loins, and therefore the procedure can have little effect on congestion of the kidney. Caution must be observed in the use of pilocarpin, as the drug may produce edema of the lung. Morphin may help to overcome this ill effect, although morphin also must be used cautiously because it diminishes the secretion of the kidney. Digitalin hypodermically he thinks of doubtful value. [O.C.H.]

Practical Therapeutics.

Under the charge of

A. A. STEVENS, A.M., M.D.

Laryngeal Tuberculosis.—Fasano (*Klinisch-Therap. Wochenschrift*, No. 23, 1900) states that he has employed Heryng's method of treatment by scraping the affected part and applying lactic acid in 15 cases. The ulcer was completely healed in 5 of these cases. In 3 of the latter there was no return after a period of 3 years; in 2 there was a relapse after 2½ years. In the other 10 cases the results were not so lasting. During the last year he has obtained better results from the use of thiolcol, which he applies locally and administers internally. The following insufflation is recommended:

R.—Thiolcol..... 1½ to 2½ grains.
Cocain hydrochlorate..... 6 grains.
Boric acid..... 15 grains.

In 3 cases of primary laryngeal tuberculosis he obtained a speedy and permanent cure with this method of treatment. Of 11 cases of secondary laryngeal tuberculosis there was rapid healing in 7, and considerable improvement in the other 4.

Drug Values as Observed in the Treatment of 752 Cases of Whooping-Cough.—Kerley (*Archives of Pediatrics*, April, 1900), concludes: 1. That every case of whooping-cough may be ameliorated by modifying the severity or by diminishing the number of paroxysms. In many cases both the severity and the number of paroxysms may be favorably influenced. 2. That remedies sedative in character, with fresh air, furnish the best results. 3. That if a remedy is to be of service its beneficial effects will be noticed in 24 hours, always within 48. 4. That the best results are obtained when antipyrin and bromid are commenced at the height of the paroxysmal stage, and then pushed. 5. That these remedies being sedative in character, the effect may be lost in a prolonged case requiring a change of treatment. 6. That children may have whooping-cough and never whoop.

Psoriasis.—Dublitz (*Journal de Méd. de Paris*) recommends the following:

R.—Oil of cade..... 2 drams.
Zinc oxid 3 drams.
Vaselin 1 ounce.

The Treatment of Thrush.—Escherich (*Rev. Men. des Mal. de l'Enfance*, June, 1900), suggests the following method of treating thrush in infants. A small pledget of sterile cotton is thoroughly impregnated with about 3 grains of finely pulverized boric acid and to which a little saccharin has been added. The pledget is then placed in a little bag made of silk and given to the child to suck. The saccharin being pleasant, the child is quite willing to retain the sac in the mouth, and so the boric acid acts continuously upon the parasite. A new sac is used each day. Cure is said to be promptly effected.

The Association of Trional with Paraldehyd.—Ropiteau (*Thèse de Paris*, 1900) states that trional is freely soluble in paraldehyd, and that the mixture is 4 or 5 times as active as a hypnotic as trional alone. The following formulas are recommended:

R.—Trional..... 15 grains.
Paraldehyd 30 grains.
Oil of sweet almonds 4 drams.

R.—Solution of trional and paraldehyd..... 2 to 4 drams.
Yolk of one egg.....
Milk..... 4 ounces.

To be used as an enema.

R.—Trional..... 3 grains.
Paraldehyd..... 6½ grains.
Oil of theobroma..... 1 dram.

For one suppository.

A Cream of Carbonate of Zinc.—Skinner (*British Journal of Dermatology*, May, 1900) suggests the use of carbonate zinc as a substitute for commercial calamin, since

the latter is often impure, and hence objectionable as an application to inflamed surfaces. He suggests the following combination for a cream of carbonate of zinc:

R.—Glycerite of starch }
Lanolin } of each..... ½ ounce.
Zinc carbonate }
Glycerin }

The first two are mixed together, then the second two, and last both together.

Anesthesia by the Injection of Cocain under the Lumbar Arachnoid.—According to the *Medical Review*, August, 1900, Cadol (*Gaz. H-édom. de Méd. et de Chir.*, June, 1900) states that the method holds a place between the administration of a general anesthesia and the superficial injection of cocain, and permits of major operation on the lower part of the body. Its mode of action is the temporary paralysis of the spinal cord, as if divided transversely, with perfect restoration of function after a period depending on the dose employed. Doses up to ½ grain produce anesthesia lasting 50 minutes, and this may be prolonged to 1 hour 40 minutes by doses varying from ½ to 1 grain. This is sufficient for all operations on the pelvis and lower limbs, amputations, excisions, vaginal hysterectomy, radical cure of hernia, etc. The patient is placed on his side at the edge of the operating table, he flexes his hips and knees so as to make a "broad back," thus separating the laminae of the lumbar vertebra as far as possible. A pillow is put under his loins to support the concavity between his ribs and the table, and keep the spinal column straight. The surgeon then finds the space between the third and fourth lumbar spines, through which the injection is performed. The skin having been rendered aseptic it is anesthetized by the chlorid of ethyl spray in order to avoid a reflex movement on the introduction of the needle, which by the overlapping of the lamina might prevent its entrance into the spinal canal. The needle employed is similar to that used in lumbar puncture, from 3 to 4 inches long, and capable of adjustment to a hypodermic syringe. In children a stout hypodermic needle is sometimes sufficient. The left forefinger is placed on the spine corresponding to the space chosen, and the needle is entered about ¼ inch outside it, and thrust steadily forward, being slightly inclined upwards and inwards. Should the needle encounter bone it is usually found to be the upper lamina, and it should be slightly withdrawn and introduced less obliquely. To thus impinge upon the lamina has the advantage of allowing the depth of the puncture to be gauged and by slightly lowering the point the spinal canal is readily found. When successful a drop of cerebrospinal fluid escapes by the needle, and until this takes place no injection should be made. After 8 to 10 drops of fluid have escaped the anesthetic may be injected. The solution of cocain should be freshly prepared, and very dilute, 1 or ½% being preferable to 2%. The quantity of fluid necessary with these weak solutions need cause, if desired, no fear of raising the subarachnoid pressure, but an equal bulk of cerebrospinal fluid may be allowed to run off by the needle before injection. The solution should be sterilized by being heated several times in a water bath to 60° C., and should be warmed to body-temperature before injection. The injection should be made very slowly, as it is important that diffusion should not immediately take place throughout the cerebrospinal fluid, or reach the upper nervous centers, but act on a limited portion of the cord, of which it produces a temporary physiologic section. The injection completed, the needle is withdrawn and the site covered with a little collodion. Subjective phenomena, such as tingling and numbness, commence in the lower limbs, then a sensation of cold and heaviness. Sensibility to pain first disappears, and is followed by thermic and tactile sensation. The motor system is then affected, but there is no paralysis of the lower limbs, but a loss of muscular sense, the patient being unable to localize the position of his limbs. In 8 to 10 minutes after injection anesthesia is established below the level of the umbilicus. It lasts 1 to 1½ hours, and then sensibility returns in the inverse order to its disappearance, the sole of the foot being the first affected and the last to recover. The writer regards the method as likely to have a wide field of application not only in hospital and civil practice, but in obstetrics and military surgery.

ANEURYSM OF THE HEART WITH THROMBOSIS OF
THE LEFT CORONARY ARTERY.

By JUDSON DALAND, M.D.,

of Philadelphia.

Instructor in Clinical Medicine at the University of Pennsylvania; Assistant Visiting Physician to the University Hospital; Professor of Clinical Medicine at the Philadelphia Polyclinic; Visiting Physician to the Polyclinic Hospital, and Consulting Physician to the Kensington Hospital for Women.

THE occurrence of cardiac aneurysm as a late manifestation of syphilis is so unusual and interesting that I venture to report this case, which occurred in the practice of my friend, Dr. Isaac Leopold, to whom I am indebted for the following clinical notes:

The patient was a married man, aged 54 years, and presented nothing of importance in his family nor early personal history. Twenty-seven years before his death he contracted syphilis and one of his children now shows signs of having inherited this disease. Two years before his death an ulcer appeared on the side of the tongue, extending from the tip to the base, which yielded to specific treatment. He was a chronic alcoholic for 30 years, but most of the time only to a moderate extent. The family state that 4 years before his death he nearly died of "heart trouble." One year later he suffered leukoderma of the hands, wrists, neck, face and chest, and the following year he was examined for life insurance and considered a good risk. Five years before his death he complained of occasional attacks of epigastric pain and a sense of fullness after eating. He also complained of moderate deafness, due to thickening of the membrana tympani and calcareous deposits, especially in the drum of the right ear. The nasopharyngeal mucous membrane showed atrophic changes. Later the leukodermic areas became darker in color.

He retired one evening in his usual good health and spirits, but complained of wakefulness and restlessness during the night. At 6.30 the following morning he was unconscious, the lips, face and finger tips cyanotic, and the feet, face and surface of the body cold. There was no radial pulse and the heart-sounds were indistinguishable. Respirations were shallow, regular and numbered 25 to the minute. The pupils were contracted and gave no response to light. A few moments later he arose to a sitting posture and endeavored to leave the bed, stating that he desired to use the commode. After voiding a large stool he again became unconscious, with complete muscular relaxation, and the attending physician thought he was dead. The free use of strychnin and brandy hypodermatically, and strong counter-irritation over the precordia was followed by partial reaction. Vomiting then occurred and each act of emesis was followed by syncope. Again recourse was had to the hypodermatic use of brandy, strychnin, aromatic spirits of ammonia, and a rectal injection of hot water; and the pulse, which had disappeared, could now be felt at the wrist. The pulse-beat from 25 to 30 a minute between 7 and 8.15 A.M., but no distinct cardiac sounds were audible. The respiratory sounds were clear in the anterior portion of the chest, but over the base there were moist rales. Nitroglycerin, in doses of $\frac{1}{16}$ of a grain, aroused the patient on one or two occasions and appeared to lessen the lividity of the extremities. The skin was not clammy, but the entire exterior of the body was cold from the beginning of the attack until death.

Two hours after the onset of this attack his family physician arrived, at which time the patient was able to converse and stated that he felt very bad, but had no pain, excepting that produced by slight burns from a hot water bottle used as a counter irritant in attempting to arouse him from his syncopal attacks.

Every 15 to 20 minutes there was an unsuccessful attempt to urinate and, by the introduction of a catheter, a half-ounce of a clear, pale urine, containing no albumin nor sugar, was secured. After an injection of nitroglycerin, $\frac{1}{16}$, and strychnin, $\frac{1}{16}$, the pulse fell from 40 to 30, and the

cyanosis disappeared, but returned upon the slightest exertion. He was catheterized at 7 and 11 P.M., but no urine was obtained. Vomiting persisted at varying intervals during the entire day, and was chiefly composed of yellow mucus, which, upon one occasion, was slightly blood-stained. There was considerable thirst and, as water seemed to excite vomiting, ice was given.

Sixteen hours after the beginning of the attack the patient was resting fairly well, but the face and finger tips were still cyanotic, the extremities cold, the pulse beating at the rate of 55 a minute and, at times, disappearing. The mind was clear, the pupils small, and there was a constant disposition to vomit and frequent unsuccessful attempts to urinate. Three hours later the patient's distress increased, the radial pulse disappeared, the extremities were cold, cyanosis deepened and respirations averaged 45 to 50 a minute. While discharging into a bed-pan, three tablespoonfuls of dark, bad-smelling blood, he suddenly expired.

The autopsy was performed at midnight, 20 hours after death, with the assistance of Dr. Isaac Leopold. The body was of moderate size and weighed about 148 pounds. The ascending vena cava was overfilled with dark, venous blood. The thoracic aorta showed advanced deforming endarteritis and a few calcareous plates. The orifice of the right coronary artery was almost occluded by a deposit of lime-salts and was only sufficiently large to permit the passage of a very small probe, of the thickness of a hairpin. The wall of this artery throughout its entire length was greatly

FIG. 1.—Extreme tortuosity of the right coronary artery.

FIG. 2.—The right coronary artery laid open so as to make visible the masses of fibroid material in the wall, which projected into the lumen of the vessel to such an extent as to cause almost complete occlusion. When the artery was emptied of blood a very fine probe could be passed through it by lifting the thinner portion of the wall away from these masses.

FIG. 3.—(A) A moderately tortuous left coronary artery, the shaded portion of which represents the regions filled by a thrombus; (B) shows the location of an area of chronic pericarditis, immediately overlying the aneurysm of the heart.

thickened and in places the vessel is twisted upon its own axis. (See Fig. 1.) About two inches from its origin there was a localized, irregularly shaped mass of soft atheroma, about $\frac{1}{4}$ of an inch in length, and immediately below this was another, somewhat similar in size, shape and appearance. These masses almost completely occlude the lumen of the vessel. With the greatest difficulty a very small probe could be passed through this portion of the artery by lifting away the anterior wall of the bloodvessel. (See Fig. 2.) During life the stream of blood flowing through the artery must have been very small. The left coronary artery was patulous, of a normal caliber, and the walls showed well-marked fibrosis. Below this point, where the left coronary artery gives off the left interventricular branch, the vessel is entirely occluded by a thrombus, which extends for a distance of one inch. (See Fig. 3.)

The left auricle was moderately dilated, its muscular walls slightly thickened and here and there were localized areas of fatty degeneration.

The left ventricular cavity was moderately dilated and the walls hypertrophied, measuring fully 1 inch to $1\frac{1}{4}$ inches in

thickness. The muscular fiber was of fair consistency and there was evidently considerable fatty degeneration. The columnar carneæ and papillary muscles showed hypertrophy. On the interventricular wall of the left ventricular cavity there was a large white fibroid patch, measuring 2 by 2½ inches, irregularly rounded in shape. Most of the interventricular septum is included in this region of fibroid degeneration. The septum was reduced to ½ of an inch in thickness. This sclerosis extends through to the right ventricle, where it is visible as an irregular fibroid area, measuring 1 inch by ¾ inch, with the long diameter corresponding to the long axis of the heart, and extending well down to the extreme apex of the right ventricle. One of the fleshy columns passing from this patch to the opposite wall had also undergone the same change. The fibroid degeneration of the interventricular septum and wall of the left ventricle had permitted a sacculated dilation of two-thirds of the septal side of the left ventricular cavity to take place, into which could be placed a large English walnut. (See Fig. IV.) The pericardium at the base of this sacculatation was firmly attached to the parietal pericardium by an old, firm adhesion, covering an area about the size of a silver half-dollar. (See Fig. III, B.) At the extreme tip of the left ventricular cavity, corresponding to the left apex, there was an area of ulceration, which had involved the endocardium and

FIG. 4.—The left ventricular cavity; the darker portion shows the aneurysm and dilation of the apex, covered with a thrombus.

myocardium, having a diameter of about ½ inch, to which was attached a fresh thrombus and, when this was removed, an old thrombus partially decolorized was revealed. (See Fig. IV.) The base of this region was composed of thick, fibrous tissue, over which is spread a thin layer of fat, and constitutes, anatomically, the extreme tip of the apex.

The aortic valves were normal and competent, as shown by the water test. With the exception of a small yellow patch of soft atheroma, at the base of the anterior leaflet of the mitral valve, these valves and orifice were normal. The right auricular and tricuspid valves and orifices were normal, as was also the right ventricular cavity with the exception of the sclerotic area already described.

The lungs showed marked edema, but were otherwise normal. The kidneys, with the exception of congestion, showed no pathologic change. The liver was slightly enlarged and its consistency was increased. The under surface of the left lobe showed a small scar. The gallbladder contained a small quantity of bile, black in color, and also a small quantity of mucus, in which were found six small gallstones, faceted and presenting a mulberry appearance. The spleen was three times its normal size, but otherwise normal. The omentum was loaded with fat. The stomach, duodenum, and jejunum were normal, but, in the region of the ileum, the mucous membrane showed acute inflammatory changes.

The brain, so far as size, shape and appearance of the con-

volution were concerned, seemed normal. The pia mater, covering the cerebrum, was opaque and thickened. There was a moderate serous exudate and the arteries forming the circle of Willis showed numerous small, white patches of atheroma. Further examination of the brain was negative and no cerebral nor meningeal hemorrhage was present.

A study of recorded cases shows that fully 60% of all cases of left ventricular aneurysms occur in the region already described.

Examination of the 81 cases reported by Legge¹ shows that the greatest number occurred between the ages of 51 and 60, in which class this case would fall.

In 85 of the 87 cases reported by Pelvet² the apex was the seat of the aneurysm.

Fifty-nine of the 74 cases of cardiac aneurysm reported by John Thurnam³ affected the left ventricle, of which 9 were the size of a nut, 20 the size of an English walnut, 7 the size of a fowl's egg, 14 the size of an orange, and 9 the size of the heart. Here again this case agrees with the rule that the majority of aneurysms of this region are the size of a walnut. In 25 of these 74 cases the wall of the aneurysm was composed of the endocardium and pericardium, which was true in this case; and in 21 cases pericardial adhesions were observed. In the 24 cases in which the mode of death was stated, none was reported as having been caused by a thrombus.

Certain of the cases reported by Dr. Whiphan⁴ resemble the one here described in the total absence of previous cardiac symptoms and the occurrence of sudden death.

Rokitansky⁵ reports 6 cases of aneurysm of the left ventricular cavity, 3 occurring in men and 3 in women, between the ages of 70 and 74, and, in 2 cases, the aneurysm encroached upon the right ventricular cavity.

Most authors are agreed that aneurysm of the heart is more frequent in the male than in the female, and that rupture is not uncommon.

Dr. Wills⁶ reports a case of cardiac aneurysm the size of a pigeon's egg, the walls of which were calcareous and the cavity completely consolidated.

Dr. Ludvig Hektoen⁷ reports a case of sudden death due to embolism of the left coronary artery.

Dr. J. G. Taylor⁸ reports a case of sudden death, occurring in a woman aged 25 years, due to obliteration of the right coronary artery at its origin.

That syphilis existed 27 years before death is clearly shown by the history of the case, and that the syphilitic virus continued to exert its effects up until a few years before his death, is also proved from the appearance of hereditary syphilis in one of his children. The occurrence of a lingual ulcer two years before his death, which promptly yielded to specific treatment, also corroborates this view. It is more than probable that the chief cause of the widespread disease of the arteries was this same poison, but it must not be forgotten that chronic alcoholism also acted as a contributory etiologic factor. It is quite likely that the cardiovascular changes began years before his death and were slowly progressive. The almost complete substitution of fibroid for muscular tissue in the interventricular septum began months or years before the symptoms of his last illness.

The extreme obstruction of the right coronary artery, near its orifice, which was narrowed to the size of a hair-pin, and the localized thickening of the wall of this vessel, must have required months or years, during which time there was a progressively increasing interference with the supply of blood to that portion of the

heart supplied by this artery, constituting a reasonable explanation for the development of the fibroid changes in the septum and later of the occurrence of the aneurysm. It is particularly interesting to note the method by which nature attempted to strengthen the weakest portion of the wall of the left ventricular cavity, above the apex, by the formation of an organized clot on the ventricular side and of chronic localized pericarditis upon the pericardial side of the heart. Despite similar changes in the left coronary artery, no symptoms were complained of by the patient, with the exception of an indistinct history of heart trouble 4 years before death, and no abnormality was detected 3 years before death, at which time he was examined for life insurance. It is also true that the heart was able to meet all the ordinary demands of life, and it seems clear that the occurrence of sudden death, in 20 hours after the first symptoms of cardiac failure, is best explained by the slow formation of a thrombus in the left coronary artery, which finally completely shut off the blood-current from the region supplied by this vessel. In view of the widespread changes in both coronary arteries and the extensive secondary changes in the myocardium, it is interesting to observe the complete absence of cardiac pain or angina pectoris. This case clearly shows that widespread and advanced coronary and myocardial changes may take place without producing a single cardiac symptom, and it also shows how easily these changes are overlooked when the heart is examined, as is demonstrated by the fact that 3 years before his death he was considered a good risk by a life-insurance examiner. This case also demonstrates the necessity of thorough, complete, and long-continued specific treatment in every case of syphilis.

THE TREATMENT OF SYPHILIS—A NEW AND TOLERABLE FORM OF ADMINISTERING MERCURY, WITH REPORT OF 65 CASES TREATED AT BELLEVUE HOSPITAL.

A Preliminary Report.

By WINFIELD AYRES, M.D.,

of New York.

Instructor in Genitourinary Surgery at the New York Post-Graduate Hospital, and Attending Genitourinary Surgeon at Bellevue Hospital, Out-door Patients' Department.

My attention was called to mercuriol nearly a year ago, when it was highly recommended as an antiseptic and of special value in the treatment of gonorrhea, one of the properties claimed for it being that it was non-irritant. As such, it occurred to me that it would be a first-class preparation for the treatment of syphilis. Until then, so far as I am aware, the medicine had never been used as an internal remedy, and some time was necessarily spent in finding the proper dosage. I began with $\frac{1}{2}$ of a grain three times daily, and gradually increased the dosage until it was found that the average amount required to control the disease was 3 grains.

The highest amount I have given is 7 grains, and the lowest amount I have found to control the disease is $\frac{1}{2}$ a grain. In starting a patient on a course of mercuriol I would advise beginning with half-grain or grain doses. Salivation has been produced by 2 grains; and yet several patients have taken as high as 6 grains with no disagreeable symptoms. The same may be said of mercuric chlorid; one patient may require $\frac{1}{4}$ of a grain, while the next will require only $\frac{1}{8}$ of a grain, to control the symptoms.

A short review of the preparations now in general use may not be out of place. Unguentum hydrargyri is followed by the best results in secondary syphilis; but no patient can properly use it himself, and it is extremely nasty, so that very few will submit to that course of treatment. The pills of mercuric protoiodid are probably used more than any other remedy at the present time. I rarely use it myself, owing to its irregularity of action and to the fact that it is so apt to cause gastric and intestinal disorder. Furthermore, 33% of the cases are not benefited by it in the least. What I have said of mercuric protoiodid applies also to the tannate. The chlorid gives much better results; yet it must be administered well diluted, and it frequently causes gastric irritation.

Mercuriol is a nucleid of mercury. It was discovered by Dr. Karl Schwickerath, of Bonn, Germany. Shortly after I began my experiments, Dr. Kopp, of Munich University, entered on similar investigations, and in a letter he has sent to Dr. Schwickerath he says:

DEAR DOCTOR:—May I ask you to send me a large quantity of those chocolate-coated tablets of mercuriol for further experiments? These tablets have rendered me such good service in the treatment of a few cases of secondary syphilis that I desire to continue my researches in that direction. However, large doses are required—10 to 12 tablets a day, which, by the way, are very well borne.

Dr. Kopp's dosage was much smaller than I have been using; probably it was about a $\frac{1}{4}$ grain a day. I think he will find, as I have done, that is desirable to use a much larger dosage. Dr. Kopp is the director of the Royal Polyclinic for Genitourinary Diseases, and has the reputation of being an excellent authority and a rather conservative man.

At present I would not advise giving mercuriol in solution with potassium iodid for the reason that there are still some doubts as to the best method of rendering it stable in this form.

My experiments were begun at my clinic in Bellevue about 2 months ago. Since that time 65 cases have been put on mercuriol, in all but 5 of which the patients had taken no previous treatment. Of these, 13 did not return after the first or second visit, 14 did not remain long enough under treatment to give the preparation a fair trial, and 13 may be described as new patients. This leaves 25 who have been sufficiently long and regular in their attendance to enable me to say something of the results obtained.

CASE 1.—This patient had a chancre behind the corona, involving the glands. He was suffering from chronic alcoholic gastritis. On June 5 he was put on mercuriol, $\frac{1}{2}$ grain three times daily. He was continued on this until July 5, when a general papular eruption appeared on the body. The chancre had healed, but still showed sclerosis. He was then given 1 grain of mercuriol three times daily. One week later he reported again, not having had medicine for 3 days. The eruption was decidedly worse—macular, papular, pustular and squamous syphilids covering the entire body, and there were several squamous syphilids on the face. He was

given $1\frac{1}{2}$ grains of mercuriol three times a day. Nine days later his eruption had begun to fade. He was given 3 grains of mercuriol hypodermically. He did not appear again for a week, when he was again given 4 grains hypodermically. Three days later he returned with an abscess over the site of the last hypodermic injection. The first injection, I may mention, was given subcutaneously; the second directly into the gluteal muscles. The eruption had faded to a marked extent. As I did not administer the hypodermic injection myself I am not positive as to the technic. August 9: The patient has not returned since July 31. This case is unsatisfactory because of irregularity of treatment.

CASE 2.—This patient had a chancre at the penoscrotal junction, and condylomata about anus, with macular and papular eruption on the body and face, and mucous patches on the tongue. On June 5 he was put on $\frac{1}{2}$ grain mercuriol three times a day, the dosage thereafter being steadily increased. Improvement began when he was taking $\frac{1}{2}$ grain three times a day, and I continued to increase the dosage until at the end of a month he was taking 2 grains three times a day. By this time all his symptoms had disappeared, and his hair, which had been falling out, had begun to grow again. August 9: There are no signs whatever of the disease and the hair has nearly returned; no intestinal or gastric symptoms; he is now taking 3 grains three times a day.

CASE 3.—This patient came to the dispensary on November 23, 1899 with a hard chancre. He afterward developed secondary eruption and marked alopecia. June 9: He has been taking $\frac{1}{2}$ grain of mercuric chlorid ever since (his limit being $\frac{1}{2}$ grain), with the result that all eruption has disappeared from the body, but he has a marked moth-eaten scalp, with a deep mucous patch on each side of the tongue. He was put on $\frac{1}{2}$ grain of mercuriol, which was gradually increased until he was taking 6 grains three times a day, with the result that his hair returned perfectly, and the mucous patches were decidedly improved, though not healed. August 7: The mucous patch on the right side of the tongue is entirely healed, that on the left side decidedly improved.

CASE 4.—The patient has no history of chancre, but had gonorrhea four times. About three months ago he noticed spots appearing on legs, also sore throat, and hair beginning to fall out. *Status praesens*, June 9: Papulo-pustular syphilid on legs, moth-eaten scalp; axillary, cervical and inguinal adenopathies. He was started with $\frac{1}{2}$ grain mercuriol, which was gradually increased until 4 grains was taken, when the hair stopped falling and the eruption began to fade. On July 21 I noticed that he had deep syphilitic ulcers in the tonsils. Mercuriol was increased to 6 grains. On the 24th slight salivation was observed and the medicine was cut off. On the 31st he was again put on mercuriol, the dosage being 5 grains taken three times a day. On August 4 the ulcers on tonsils were nearly healed, the eruptions on legs had almost entirely faded, and the hair had begun to grow. On the 7th he complained of diarrheal movements every two hours with some cramps, when the medicine was stopped and he was given bismuth subnitrate. August 9: The ulcers are entirely healed; eruption has disappeared; diarrhea entirely checked; he was given 5 grains mercuriol three times a day.

CASE 5.—This patient had a chancre beneath the prepuce which could be felt but could not be seen. It appeared one month after connection and on June 14 had been present for three months. The patient had inguinal, epitrochlear, and cervical adenopathies, also a pustular syphilid over right groin. He was started on $\frac{1}{2}$ grain of mercuriol, which was gradually increased until 6 grains were taken three times a day. Two days after he had been taking the latter quantity the bowels became very loose and the patient ceased taking more than 5 grains at a time. One week later the gums became slightly spongy and red, and his medicine was reduced to 3 grains three times a day. August 9: The inguinal adenitis has decidedly diminished in size. The sclerosis of the chancre is also less. The eruption has entirely disappeared.

CASE 6.—About May 1 this patient had a sore on the penis followed by roseola. For two weeks before coming to me he had been taking nine protoiodid pills daily. *Status praesens*, June 14. Inguinal adenitis, headaches, mucous patches on tongue, and pains just below the knee, coming on in the afternoon. I put him on mercuriol $\frac{1}{2}$ grain. Two days later

the pains had disappeared. No change in eruption. Medicine was gradually increased until July 10, when he was given 3 grains three times daily. Under this treatment the eruption gradually disappeared, but the mucous patch in the throat still persisted. On August 2 he was taking 7 grains, and all his symptoms had disappeared, except a mucous patch on the right tonsil. August 9: There are no signs of syphilis, but he has slight diarrheal movements with a little colic; medicine is cut off and bismuth subnitrate given. When he resumes he will get 5 grains three times daily.

CASE 7.—When he came to the dispensary he had a chancre in the culdesac four months previously, and had been taking $\frac{1}{2}$ grain of mercuric chlorid for one month. *Status praesens*, June 16: Mucous patches on anus and tongue. Put on $\frac{1}{2}$ grain of mercuriol, which was increased until he was taking 1 grain, under which the mucous patches began to disappear. The process of gradually increasing the dosage was continued until he was taking 3 grains three times daily, when the tongue was entirely healed and the mucous patch about the anus had disappeared. August 2: For the last two weeks he has been taking 3 grains three times daily, with no return of the symptoms. August 7: There is no sign of the disease, except that the hair is still falling; 5 grains three times daily.

CASE 8.—This man had no history of chancre. *Status praesens*, June 16. General eruption on body, headaches, severe pains in bones. This patient was put on $\frac{1}{2}$ grain of mercuriol, and under that small dosage the eruption began to disappear, and the pains also, but medicine was increased steadily. On July 14 he reported with gonorrhea, and was given in addition Mixture Lafayette. At that time he was taking 2 grains mercuriol three times daily. On the 21st he reported no appetite and some vomiting, which was probably due to the Mixture Lafayette. There were no symptoms of syphilis. The mercuriol was continued, and he reported again on the 26th with a mucous patch on the under lip, and unable to retain either Lafayette or mercuriol; he was given 4 grains mercuriol, cutting off Mixture Lafayette, and came back on August 7 with gums slightly inflamed, and mucous patch still persisting on under lip. August 9: The gums were in normal condition, mucous patch slightly better; he was given 5 grains three times daily.

CASE 9.—This patient had a chancre on the cervix of the penis, extending the entire circumference; he complained of afternoon headaches. On June 19 he was given $\frac{1}{2}$ grain of mercuriol three times daily. Four days later the patient was given $\frac{1}{2}$ grain. On July 3, roseola appeared over the abdomen, and the dose was increased to $\frac{1}{2}$ grain three times daily. On July 10, the eruption changed to macular with pain over the heart; he was given $1\frac{1}{2}$ grains; eruption has begun to fade slightly; pain over the heart has disappeared; 2 grains. July 21: The eruption has entirely disappeared, but there are mucous patches on both tonsils; 3 grains. August 4: He still has mucous patches in the throat; medicine increased to 5 grains three times daily.

CASE 10.—Chancre in January; seven weeks later eruption; sores in the mouth one month afterwards; treated in dispensary with mercuric chlorid $\frac{1}{2}$ grain; some improvement. On June 21 has had no treatment for two weeks; tongue on both sides covered with mucous patches, with deep fissures running into the tongue from the sides; he was put on $\frac{1}{2}$ grain mercuriol, and the dosage was increased steadily until he was taking 2 grains, when improvement began to be noticed. On July 14 he was given 4 grains. July 21: The tongue is entirely healed; I have never seen a tongue in such a condition improve so rapidly under any other antisyphilitic treatment. August 2, he was still taking the medicine regularly (4 grains 3 times a day) with signs of the disease.

CASE 11.—Had two chancres on penis, which began two days after connection, and on June 23 had existed for about three months; two weeks before this date he began to have general pains in the body. *Status praesens*: Two sclerotic nodules on the left side of penis; mucous patch on scrotum; general macular eruption; severe pains all through the trunk especially in the back, much worse at night; he was put on $\frac{1}{2}$ grain mercuriol three times a day. In the course of the following week the dose was increased to 1 grain, and his pain not having been relieved I asked the doctor in charge

of the medical room to see him; he thought the pains were probably due to malaria; large doses of quinin and phenacetin failed to give relief, as did also small doses of morphin, so that I was obliged to consider that the original diagnosis of syphilitic pains was correct, and he was kept on increasing doses of mercuriol. The result was that on July 10, when he was taking 3 grains, the chancre had nearly disappeared and the eruption had entirely vanished. The dosage was steadily increased until he was taking 7 grains, and he became slightly salivated on July 28; medicine was then cut off. On August 2 the pains had somewhat increased, the chancre, however, had disappeared and there were no signs of eruption. August 4 he showed a mercurial ulcer near the last molar on the under jaw, on the left side; the medicine was stopped, and he was given 15 grains of potassium iodid, increasing to 30 grains three times a day. On August 9 he reports no relief of his pains; ulcer of his gum improved; given tincture of myrrh locally and 30 grains potassium iodid internally. I consider this man a neurotic, who unquestionably exaggerates his pains to a great extent.

CASE 12.—This man gave a history of indiscriminate connection before sore appeared on the penis, which had persisted about two weeks; no pains. *Status praesens*, July 3: Sclerotic erosion about the size of a dime in the culdesac of the prepuce; glands on the right side enlarged to the size of a walnut, others normal; slight macular eruption. He was put on $\frac{1}{2}$ grain mercuriol, increasing gradually until July 24, when he was given 4 grains. August 2 he reported that the eruptions had entirely disappeared, chancre healed, though small sclerotic nodule still remained. August 9, body perfectly clear, no sign of the disease anywhere, taking 4 grains three times daily.

CASE 13.—This patient was treated at the dispensary May, 1900, for chancre with roseola, no pains. *Status praesens*, July 5: Mucous patch on the penis, inguinal adenitis; given $\frac{1}{2}$ grain mercuriol three times daily, increased to 1 grain. On July 17, after he had been taking 1 grain for a week, slight salivation was caused; the mucous patch had healed, and the adenitis had nearly disappeared. On July 28, his gums were still inflamed, while the adenitis was continuing to disappear. On August 7 the teeth and gums were in good condition; mucous patch had reappeared on penis; inguinal adenitis decreasing slowly in size; given $\frac{1}{2}$ grain three times daily.

CASE 14.—This patient came to the dispensary on July 5; he had had a chancre about 3 months before, followed by macular eruption, which had entirely disappeared; has been taking $\frac{3}{4}$ grain mercuric chlorid, and afterwards $\frac{1}{2}$ grain protoiodid. *Status praesens*: Hair continues to fall out, though not markedly; bowels very loose; put on mercuriol, 1 grain, gradually increased to 3 grains. Reported July 17, when I found a mucous patch on the anterior surface of the left anterior pillar of the fauces; he still had glandular enlargement; he was slightly salivated, and had mercurial breath; he was given, in addition to mercuriol, potassium chlorate. August 4: The throat is decidedly improved, no sign of salivation; given 4 grains mercuriol three times daily.

CASE 15.—The patient came to the dispensary on July 7 with a sore on the penis, which had existed about a month, and gave a history of indiscriminate connection. *Status praesens*: There is a dry nodule underneath the foreskin about the size of a dime, and $\frac{1}{2}$ of an inch thick; macular eruption appearing on the body; inguinal adenitis; he was put on 1 grain mercuriol three times a day, the dose being increased gradually. July 14: He was given 3 grains three times a day. July 17: He reported that the eruption had disappeared, and that the chancre was slightly diminishing in size; 4 grains produced salivation. July 28: there was no sign of the eruption, but gums were still slightly tender.

CASE 16.—This man came to the dispensary January 2 with gonorrhea and chancre; eruption appeared about a month later; has been taking $\frac{3}{4}$ grain mercuric chlorid three times a day ($\frac{1}{2}$ grain being his limit). *Status praesens*, July 10: He has palm-syphilid in both hands, squamous variety; he was given $1\frac{1}{2}$ grain mercuriol, increasing until he was taking 3 grains. Four days after being put on this dosage his hands had almost entirely healed. August 7: Eruption on hands entirely disappeared; taking 3 grains.

CASE 17.—The patient had 2 chancres, one on the frenum, and one on the preputial margin; chaneroid on the dorsum

of the penis; chaneroid appeared about a week, and chancre three weeks, after connection; no eruption, but had pains in the bones, and headaches in the afternoon; no sores in the month. July 10: He was put on 1 grain three times daily. July 14: He reported no pains; chancre healed, though still indurated. July 17: He had a few syphilitic eruptions distributed over the body; dose of mercuriol increased to 3 grains. August 2: All eruptions on the body had entirely disappeared; sclerosis of the chancre diminished in size; syphilitic angina. August 4: Mucous patch appeared on the right tonsil; given 4 grains three times a day. August 9: Throat decidedly improved; has been taking on an average 10 tablets per day, 1 grain each.

CASE 18.—The patient was treated at the dispensary two months ago for chaneroid, and reported on July 12 that two weeks previously he began to notice an eruption. *Status praesens*: Sclerotic nodule on side of penis; general papular eruption on body and face; put on $\frac{1}{2}$ grain of mercuriol, the dosage being increased steadily until, on July 24, he was given 4 grains three times a day. On August 2 the report was: Eruption slowly disappearing, sclerosis of chancre nearly gone; he is now taking 5 grains three times daily.

CASE 19.—This man had chancre one year ago, the eruption appearing one month afterward; he came to the dispensary in February with squamous and ulcerative syphilids over body and face; he has been taking since then $\frac{1}{2}$ grain mercuric chlorid and 15 grains potassium iodid, with the result that the eruptions had disappeared materially though not completely. *Status praesens*, July 14: Thickened red patches on the face covered by scaly eruptions; 4 grains mercuriol and 15 grains potassium iodid. July 26: He reported that medicine had lasted for one week and during that time the eruptions on the face had almost entirely disappeared; he was unable, however, to come to the dispensary to get the medicine renewed, and the consequence was the return of the eruption, which is now in much the same condition as on the 14th; he was given 5 grains mercuriol and 15 grains potassium iodid. July 31, very slightly improved. August 4: The thickening at the site of the old eruption on the face has almost entirely disappeared; 5 grains mercuriol with 15 grains potassium iodid.

CASE 20.—No history of chancre, though he had had several chaneroids. *Status praesens*, July 17: Macular eruption; inguinal, right epitrochlear, and postcervical adenopathies. Started on 1 grain mercuriol, increasing steadily until on the 21st he was given 4 grains three times a day. On the 24th he developed a mucous patch on the under surface of the tongue; he was given 5 grains. July 28, he had tenderness of the teeth, redness of the gums; mucous patch on the cheek; the eruption had disappeared, except one small spot on forearm. July 31, his body was absolutely clear; he was given 3 grains. On August 2, the mucous patch on the cheek had improved; the body was perfectly clear; still a few adenopathies. August 9: Mucous patch on the cheek entirely healed, still a little syphilitic angina; continued on three grains.

CASE 21.—The patient came to the dispensary on July 21 reporting that he had had chancre about three months before; the old scar of the chancre persisted; he had a mucous patch on inner side of the cheek and another on the under side of the penis; there were condylomata about the anus; he was started on 2 grains, gradually increasing until he was taking 5 grains. On August 2, the teeth were slightly tender; mucous patch on the inner side of the cheek still present, treatment was stopped for one day, and then continued. August 9: This case has shown wonderful improvement; the mucous patches have almost entirely disappeared; he is taking 5 grains three times a day.

CASE 22.—No history of intercourse since February, at which time he had sores which were evidently diagnosed as chancre; he had a few eruptions on body; the sores and eruption entirely disappeared under internal medication. *Status praesens*, July 21: For the last 5 weeks has had a sclerosis extending from the right side of the frenum around about an inch to the left side; this sclerosis is a typical chancre, consequently the primary diagnosis must be doubted; he has pains in bones, worse at night; 2 grains of mercuriol was prescribed. This was gradually increased to 4 grains with the result that the sclerotic nodule on the penis decreased in size. August 7: The pains in the bones are almost entirely relieved; he is taking 4 grains three daily.

CASE 23.—This patient applied for treatment on January 15; examination showed that he had a chancre on the scrotum; two weeks later an eruption was noticed on the body; there was inguinal adenitis; the hair fell out to a slight extent; there were mucous patches in the throat and mouth which were entirely removed by $\frac{1}{8}$ grain mercuric chlorid three times a day. He continued on this treatment until June 9. *Status præsens*, June 29: Mucous patches on the tonsils for the last 3 weeks; he was given $\frac{1}{8}$ grain mercuriol. This was gradually increased to 1 grain three times a day, and the mucous patches entirely disappeared by July 19. August 9: Did not return for his medicine from the 21st ult., has been out of it for 10 days; shows slight return of syphilitic angina of the throat; put on 1 grain three times a day.

CASE 24.—This patient came to the dispensary on January 2 with a sore which was at first thought to be a chancre, but was afterwards diagnosed as a chancre; he was put on $\frac{1}{8}$ grain mercuric chlorid, with the result that his symptoms all disappeared except the sclerotic nodule; he stopped medicine about June 1. *Status præsens*, June 21: Phimosis with indurated nodule underneath; macular eruption all over body; general adenopathies; mercuriol, $\frac{1}{8}$ grain three times a day. On July 18 he reported that the medicine had caused nausea and cramps, giving him three movements a day; at this time he had been taking 1 grain. He was increased to $1\frac{1}{2}$ grains; July 24, the eruption had entirely disappeared; no intestinal or gastric disturbance. On August 4 he returned with his body perfectly clear, with some discharge under the prepuce, but phimosis and the sclerotic nodule persistent. August 7: There are no signs of eruption, but chancre persists; he is taking 2 grains three times a day.

CASE 25.—This patient came to the office on June 15 with a history that about 2 weeks previously he had noticed a small sore on the foreskin. When I first saw him he had induration on both sides beneath the prepuce, phimosis, general adenopathies, macular eruption on the body, and pains in the left knee. I put him on $\frac{1}{8}$ grain mercuric chlorid three times daily, and gradually increased the dose until he was taking $\frac{1}{4}$ grain, when he became salivated. It had no effect on the eruption whatever, though the sclerosis of the chancres had disappeared to quite a marked extent. On July 9 I gave him $2\frac{1}{2}$ grains mercuriol, and afterwards increased it 3 grains. July 30, the eruption had entirely faded from the face and was rapidly disappearing from the body; he complained of the syphilitic numbness of the fingers; the gums on that date were slightly tender; ordered $2\frac{1}{2}$ grains. On August 6 the patient reported that by mistake he had taken $12\frac{1}{2}$ grains three times daily for two days; this caused no disturbance of the stomach or diarrhea, but the teeth became tender and gums swollen; he stopped medicine for one day, and then took 8 grains a day. Two days after this visit the teeth had again become tender, and he had taken no medicine since. The eruption had entirely disappeared from the body, and there were no signs of syphilis anywhere. The gums were slightly red and tender, and the teeth also tender. He was given $2\frac{1}{2}$ grains three times daily with a mouth-wash consisting of tincture of myrrh 2 ounces, potassium chlorate 1 ounce, water 2 ounces.

In conclusion, I would remark, of course, 2 months is not a sufficient time to judge absolutely of any medicine in the treatment of syphilis; but the marked improvement shown by many of the cases in this brief time makes it certain that mercuriol is of great value. The preparation has caused gastric irritation in only one case, Case 17; and probably if the enteric-coated tablets had been given in this case the gastric disturbance would not have occurred. Diarrhea with colicky pains is reported in 4 cases. In one of these the troubles disappeared although the dose was increased, showing that, in that case, they were not due to the medicine. In another case the patient reporting diarrhea did not return after doing so. Of the other two cases one was taking 6 and the other 7 grains three times a day, with the probability that the dose was too much.

That mercuriol is superior even to mercuric chlorid in

controlling the symptoms of syphilis is proved, in my opinion, even by this short trial. Cases 3 and 25 illustrate this perfectly. Like all preparations given internally mercuriol has very little effect on the chancre; still it has hastened the healing slightly. It seems to be much more efficient in controlling skin-eruptions than mucous eruptions.

Two further remarks may here be made. First, that the number of patients who have returned for treatment is unusually large for dispensary work. And second, that of the 25 patients whose cases have been reported on, none required to be put upon potassium iodid to control the secondaries. In Case 11 the addition of potassium iodid had no effect in controlling the pains. In Case 19 the eruption was one of tertiary variety, that is, marked thickening of the skin.

It has seemed to me in the short time that I have used mercuriol (1) that it causes less disturbance of the gastrointestinal tract than any other preparation of mercury used internally; (2) that it controls skin-eruptions and pains much better than any other preparation, while it controls mucous eruptions as well as any other, and has equally good effect on the chancre; and (3) it is an advantage that it can be taken in pill form. These three points make the preparation one of great value.

VALUE OF POTASSIUM BICARBONATE IN COLDS AND INFLUENZA.*

By STEPHEN HARNESBERGER, M.D.,
of Catlett, Va.

POTASSIUM BICARBONATE, given early, will, in nearly every instance, abort a cold very effectually and almost at once. The remedy is well borne by both elderly and weak persons. Nor is it necessary for them to keep indoors as after the treatments commonly in use. Even when the case has advanced further and fever is present, this drug, with others indicated, will help greatly to reestablish the normal adjustments of the body. In those cases in which the tonsils are involved, or in which the catarrhal inflammation affects the other air-passages, or the alimentary canal, potassium bicarbonate will demonstrate its benign influence. Pneumonia is a less frequent result in such cases, and when it does come on, I find it runs a much milder and shorter course.

But it is in influenza that I wish to speak of potassium bicarbonate as a remedy of unusual value. I began its use in this disease in the autumn of 1889, and my observations of its beneficial effects through the epidemics of influenza since that year have convinced me that it is a therapeutic agent in which we can place the utmost confidence. According to my experience influenza is the only disease which seems to weaken the adult heart-muscle primarily, or from the very outset of the attack. This is why pneumonia is so frequent a complication. The patient either succumbs to pneumonia or is left in a weak condition, with lowered digestive function and an irritable condition of the heart, physical exertion being almost out of the question. I do not attempt to explain in what way potassium bicarbonate acts, but I find that my patients taking the drug get quick relief and make a more speedy and thorough recovery. Osler, in speaking on

* Presented to Section of Materia Medica, etc., at the Annual Meeting of the American Medical Association at Atlantic City, June 5-8, 1900.

the treatment of influenza, says: "The depression following the disease is one of the most unpleasant and obstinate features." Tyson says: "Weakness following influenza may be extreme, and the slightest effort, physical or mental, promptly convinces the patient of this, and the duration of the weakness may be prolonged for months." Of course, as we all know from experience, it is this weakness or depression in the acute stage and subsequently that the danger chiefly lies. Exertion, diaphoretics, coal-tar derivatives, etc., only tend to increase the danger by still further lessening the resisting power of the system. Potassium bicarbonate, following a free action of the liver, rest, and a concentrated liquid diet is in my experience the best safeguard against the development of still more unfavorable and perhaps fatal prostration.

I give 30 grains of potassium bicarbonate in a cup of milk every 4 hours during the day, and no other diet for 48 hours, and find that this will, in most instances at least, quickly start the patient along to health. When milk is not well borne or readily taken, administer the remedy with a glass of cold water and allow only liquid diet, and in from 36 to 48 hours most patients will feel better and want to eat.

Nothing seems to assist the action of potassium bicarbonate so well as a cathartic, such as calomel, podophyllum, etc. In fact, there are cases in which it is extremely difficult to get the bowels to move on account of a temporary paresis of the muscular coats of the intestines. These patients do not show so much systemic weakness nor heart-depression, and when the functional activity of the bowels is restored they very rapidly return to health. But whether the disease affects the brain, the lungs, the heart, or the bowels, I am confident, from a considerable experience, that no treatment for influenza will do more genuine and permanent good than full doses of potassium bicarbonate.

The prognosis of influenza of a severe type is much worse in the weak and elderly, on account of the frequency and special tendency with which the heart-muscle is involved—especially the tendency to acute dilation and the liability of the attacks to be complicated with pneumonia. The tonic and resisting power of the heart-muscle in adults seems to be lowered in this disease—a striking resemblance to a like condition of the heart-muscle in children suffering from severe acute infectious diseases. To obviate this danger, cases of this character of influenza in adults should be treated with maximum doses of potassium bicarbonate, and absolute rest in bed enjoined. I have now a patient who will round up 100 years of age on September 26 next, who is doing well on potassium bicarbonate, though she showed in the outset of the attack every symptom of beginning pneumonia and cardiac failure.

LOCALIZATION OF A BULLET-WOUND OF THE SPINAL CORD; REMOVAL OF THE BULLET FROM THE SPINAL CANAL.

By HOWELL T. PERSHING, M.D.,
of Denver, Col.

Professor of Nervous and Mental Diseases in the University of Denver.

MRS. A., aged 42, was admitted to the Arapahoe County Hospital, in the surgical service of Dr. W. B. Craig, April 10, 1900. In the absence of both the visiting neurologists, it devolved upon me, as one of the consultants, to report the neurologic features of the case to Dr. Craig.

¹ Read before the Colorado State Medical Society, June 21, 1900.

On February 27, 1900, two bullet-wounds had been inflicted by her husband with a revolver at close range. One bullet passed superficially under the skin, and was easily extracted. The other entered the back about the level of the eleventh rib and 6 inches to the left of the median line; its course could not be ascertained.

At the time of the shots the woman remained conscious, but immediately fell, felt a numb sensation from the waist down and found herself unable to move either of the lower limbs. Severe pains in both buttocks and thighs soon set in. Control of the bladder and rectum was lost; the urine would accumulate for a number of hours, without dribbling, and then be spasmodically and unconsciously evacuated. These symptoms had persisted up to the time of examination.

Condition on Examination.—The muscles above the waist were under normal control, but there was complete absence of voluntary motion of all the joints of both lower limbs. Faradic irritability was entirely lost in the paralyzed muscles except a scarcely perceptible contraction of the right peroneal group. The muscles were flabby and somewhat wasted. There was a small bed sore on the right buttock.

The plantar reflex, Achilles reflex and knee-jerk were absent, but the anal and perineal reflexes were quite lively, although the irritation was not felt. All forms of sensibility were lost up to a definite line, passing across the external genitals, the front of each thigh, the buttocks and the sacrum. This line corresponded very closely with that marked in Head's diagrams as separating the sensory areas of the first and second lumbar segments of the cord. There was much complaint of pain in the thighs and buttocks, which could not be controlled without full doses of morphia.

The facts of the history and examination were not difficult to interpret. The distribution of the paralysis and sensory loss, together with loss of control of the bladder and rectum, and trophic changes made it certain that there was a lesion of the spinal cord. The limit of the sensory loss showed the upper limit of the lesion to be at the junction of the first and second lumbar segments, a part of the cord which is enclosed by the eleventh dorsal vertebra. The lowest sacral segments could not be involved because the perineal, anal and vesical reflexes, which are dependent on the integrity of these segments, were retained. That a considerable portion of the lumbar enlargement, including the lower four lumbar and at least the first sacral segments, was severely injured, was evident from the complete loss of reflexes and faradic reactions in the lower limbs.

An opinion was accordingly given that the cord was damaged at a part mainly opposite the twelfth dorsal vertebra, extending both upward and downward, but not so far as the upper border of the eleventh dorsal or the lower border of the first lumbar vertebra. This damage was evidently inflicted at the moment the shot was fired, but whether directly by the bullet itself or indirectly through fracture of a vertebra or hemorrhage could not be told. In either case it could not be affirmed that the persistence of the symptoms was due to persistent pressure on the cord. This was only a possibility, the probability being that the original damage was sufficient to account for all the symptoms, whether pressure was maintained or not.

Independently of the neurologic examination Dr. Stover took a skiagraph of the lower spine, which gave a faint and doubtful indication of a foreign body between the twelfth dorsal and first lumbar vertebrae. Dr. Stover was not willing to place much reliance on this indication, but as it harmonized with the neurologic localization it was accepted as corroborative evidence.

The patient had entered the hospital with the express purpose of having an operation performed. In consultation with Dr. Craig it was agreed, for reasons already indicated, that the possibility of restoring any

considerable degree of function was extremely slight. On the other hand, the localization was so definite and the risk attending an exploratory operation of so little moment that it was deemed wise to operate in the hope that at least the pain might be relieved. The whole matter was frankly explained to the patient and she unhesitatingly asked for the operation.

Dr. Craig operated April 21. The spine and laminae of the twelfth dorsal vertebra were first removed. Nothing abnormal could be detected except the absence of pulsation in the exposed dura. It was then decided to remove the spine and laminae of the eleventh dorsal rather than of the first lumbar vertebra, because a mechanical obstruction would be more likely to exist at the upper than at the lower limit of the lesion. This was rapidly done and the finger then detected a foreign body in the part of the spinal canal within the eleventh dorsal vertebra, a little to the right of the median line. This was seized with forceps and easily removed, when it was found to be a misshapen bullet of about 42 caliber. Nothing further was done except to dress the wound in the usual way.

On recovery from the anesthetic the patient gave surprisingly little evidence of shock and said she was to a great extent relieved of her pain. This relief continued for a number of days and much less morphia was needed than before the operation. There was no restoration of function, in spite of the patient's pathetic attempts to find some improvement in this respect, and after some days the pains began to return with their former severity. On April 29 and 30 it was noticed that the pulse-rate was rising and strength failing. Less food was taken and finally it was refused altogether. Death occurred from constantly increasing exhaustion, May 15. No postmortem examination was allowed.

This case seems to me to call for little comment. Notwithstanding the remoteness of the possibility of doing substantial good in such a case it was on the whole wise to make the attempt. The operation was rapidly and skilfully performed, and the unfortunate woman certainly lost nothing of the very little that it remained possible for her to lose.

STUDY OF A MUMMY AFFECTED WITH ANTERIOR POLIOMYELITIS.¹

By JOHN K. MITCHELL, M.D.,
of Philadelphia.

IN the Archeological Museum of the University of Pennsylvania is the skeleton of an Egyptian of a period about 3,700 years before Christ, which presents some problems of interest. Mr. Flinders Petrie found this mummy at Deshasbeh, a village on the western edge of the plain, some 80 miles south of Cairo. Although the tomb had been rilled, the style of burial indicated sufficiently that the body was that of a man of the better class. The coffin is hewn out of a single great log of sycamore; in the end the rings of growth may still be counted with ease enough to determine the tree as not less than 300 years old when it was fashioned. A straight stick, about 4 feet in length and $\frac{1}{2}$ inch in diameter, lay alongside the body, broken in three pieces. It was at once observed by Mr. Petrie that the man had one leg much shorter than the other, and he

supposed the thigh to have been broken—but, as will be seen, there is no evidence of this.

The bones, which are exceedingly light and fragile from age, have been carefully articulated and, except for certain small losses of substance where they have crumbled away, are in good preservation, and their sizes and relations are readily studied.

The skeleton is that of a small male, the extreme height being 1 meter, 63 centimeters. Making allowance for flesh and cartilage, the subject in life could scarcely have exceeded 5 feet, $5\frac{1}{2}$ to 6 inches. That he was an old man is shown by the ossification of the rib cartilages, the obliteration of the sutures in the skull, and by the much worn grinding surfaces of the remaining teeth. The general capacity of the skull, the square and well-formed lower jaw, and the facial angle, all indicate character and intellect, and confirm the belief suggested by the methods of burial and preservation that the man belonged to the educated and wealthy governing or upper class.

One notices at once that the left leg is considerably shorter than the right, and at first sight the femur of the left side seems heavier and thicker than the right one. Measurement, however, makes it evident that the left femur's apparent greater circumference is only due to its shortening, and to strongly marked ridges at the site of the muscular attachments, which suggest that the muscles may have been hypertrophied on that side. With this exception the left femur is imperfectly developed in all directions.

The left femur is 8.2 cm. shorter than the right, round the middle of its shaft it is 1.2 cm. less, and the neck is 4 cm. less in circumference. Condylod measurements could not be compared, as the left condyles are somewhat crumbled. The necks of the femora are the same length on both sides. There is no sign of fracture or injury to the bone of the left thigh. Only a very minute and practically negligible difference can be made between the bones of the lower leg on the two sides, not more than .5 cm., an amount of difference often exceeded in healthy bones, but it should be said that though the shortening is very slight, it is on the left side.

So far as can be told the bones of the feet are unaffected, but as the terminal phalanges have crumbled almost entirely away, nothing can be stated with certainty about them.

The pelvis is perfectly formed and the vertebrae present no sign of unequal or imperfect development, so that evidence is wanting of any compensatory curvature, such as might be expected in a patient who had come to old age with one leg three inches shorter than the other. These facts and the marked prominences for muscle-attachment on the surface of the short thigh-bone, suggest that during life some means of compensating for the shortening must have been used, such as a high-soled shoe or sandal might afford, the additional weight of which perhaps aided in bringing about a certain degree of hypertrophy of the thigh-muscles on the affected side. Moreover, the stick found in the coffin, as my friend, Dr. Edward Martin, who at my request remeasured the bones and examined them for evidence of injury, ingeniously suggested, is too long and slender to have served as a support and must have been merely a balancing staff.

The impossibility of cross-examination of the patient on his early history leaves us free to conjecture as to the cause of the difficulty, but nothing seems so prob-

¹ Read at the meeting of the Association of American Physicians at Washington, D. C., May 3, 1900.

able as that the defect of growth is due to an attack of poliomyelitis, perhaps even an intrauterine one. It is certainly unusual, though not unheard of, that only one segment of a limb should be affected; but this disease is notoriously apt to be irregular in its distribution; for example, when it occurs in the arms, it is sometimes limited to the upper, sometimes to the lower arm. Every one knows how constantly the anterior tibial muscles remain weak when other muscles make fair recovery from their palsy, insomuch that one is apt to depend upon this weakness as indicative of infantile paralysis where the cause of lameness is doubtful. Yet at this moment I am treating a patient in whom bilateral infantile paralysis of the anterior thigh muscles is present, while the anterior tibials on both sides are perfectly sound. No theory has been proposed which will account for the frequency with which these groups are

picked out nor indeed any one which will adequately explain why the disease should affect only the anterior cornua. What is curious is that I cannot find in the dozen great works of reference which I have consulted in the effort to settle this small point, any categorical statement as to whether the growth of one bone alone may be affected and its attached muscles escape, or be affected with it and recover later. The subject is one for larger discussion and study—and I have been concerned with the presentation only of what is, if my supposition of the causation is correct, the earliest known case of infantile palsy, although Dr. Osler has hinted his opinion² that the lameness of Jonathan's son, Mephibosheth, was due to this trouble, an opinion founded, I fear, on even slenderer basis of fact than the one here expressed.

² Osler's "Practice," Art. Infantile Palsy.

ANALGESIA IN OBSTETRICS PRODUCED BY MEDULLARY INJECTIONS OF COCAIN.

By S. MARX, M.D.,

of New York.

Treatment of the Breasts.—George L. Brodhead (*New York Postgraduate*, October, 1900), when the breasts are not to be used for nursing after confinement, advocates the following: A tight breast binder should be applied with the patient in the horizontal position, immediately after nursing has ceased (or in case of stillbirth, on the second day after labor), the nipples being protected by small pieces of sterile gauze. Cotton should be placed in the axillae, around and between the breasts, and the binder applied as firmly as the patient can bear it with any degree of comfort. When once the binder has been evenly and carefully put in place it should not again be removed, except for purposes of cleanliness, until the breasts are soft and painless, because the breasts are often very tender and painful, and manipulation tends to increase the discomfort. In many cases the binder alone will be sufficient to accomplish the end desired, the milk drying up quickly and with little or no discomfort. In other cases it will be necessary to limit the amount of fluids taken in order to reduce the distention in that way. In all cases where the breasts become caked and tender it is a good plan to administer Rochelle salts, in plain water or in vichy, a half ounce every hour until the bowels have been freely evacuated. The large watery movements will relieve the distention to a great degree, and in the vast majority of cases these measures (binder, limited amounts of fluid, and salts) will prove successful. He has relied upon the plan to the entire exclusion of massage, the use of the breast pump, hot fomentations and belladonna ointment. [G.C.C.H.]

Significance of Blood-count.—Andrew J. Coey (*St. Paul Medical Journal*, October, 1900) bases upon more than 1,000 examinations of blood, the following conclusions: In suppuration the increase of white blood-corpuscles is proportionate to the intensity of the inflammation and falls as the pus escapes. As the inflammation disappears there is a diminution of the leukocytes which may be present in subnormal amount at the time of convalescence. In obscure suppurations and especially in pus collections in the peritoneal cavity, blood-examinations are of the greatest diagnostic

value. In malignant disease a leukocytosis is usually observed. The absence of leukocytosis in uncomplicated cases is, therefore, indicative of typhoid fever, tuberculous peritonitis, gallstone or renal colic, intestinal obstruction, fecal impaction, neuralgia, etc. Carcinomas are usually accompanied by a greater or less leukocytosis. Sarcomas have always a well-marked leukocytosis. Appendicitis furnishes the most marked example of the value of the leukocyte-count as regards operation. Cases of purely catarrhal appendicitis rarely present a leukocytosis. With pain in the region of McBurney's point and a stationary or increasing leukocytosis, imperative, immediate surgical interference, whether other symptoms and signs be present or absent, is indicated. A steadily increasing leukocytosis must always be considered as a bad sign and as demanding prompt operation. He has not observed a negative count in any pus-collection with the exception of pure cold abscess. His personal experience would lead him to exclude pus with a negative count. In septicemia and pyemia the leukocyte count is about on a par with the count in appendicitis. Streptococci and staphylococci may frequently be found in blood-cultures in many forms of infection. In surgical diseases leukocytosis with a rise in temperature would exclude hysteria and mental worry. In osteomyelitis and in all abscess formations, pure cold abscess alone excepted, there is always a high leukocytosis. [G.C.C.H.]

Treatment of Uterine Carcinoma.—Stansbury Sutton (*International Journal of Surgery*, November, 1900) advocates total vaginal hysterectomy whether disease of the appendages is marked or not, thinking it the safer procedure, although in the latter case curetting, biconical section, or trachelorrhaphy may sometimes prove sufficient. Treatment of uterine carcinoma after the disease is established is a failure, the only possibility of improvement on present conditions lying in more extensive repair of the cervix in the early years of childbearing and in the inauguration of radical hysterectomy when the conditions leading up to carcinoma are discovered. [G.C.C.H.]

VOL. VI, No. 20

NOVEMBER 17, 1900

\$3.00 PER ANNUM

Mental disease in military life may be more common and more productive of evil than we think. If an insane commander is given such a position that all subordinates cannot possibly criticise or make their suspicions known for fear of the swift punishment that follows lack of discipline, insidious and awful errors and wrongs may result and may continue a long time before superior and perhaps far-away officers suspect the true condition. It is said that during a recent war a balloon was sent up which, instead of defining the enemy's position, revealed that of the general ordering the balloon, and of his troops, to a hundred gunners, who only awaited the indication to play havoc with their shells. The commander, it is further said, is now known to have been insane, his father, mother and sisters having died insane. Suppose that chronic meningitis should exist in a General entrusted with the conduct of a campaign far from the seat of the central government, and that he should have delusions of grandeur, with other symptoms of profound but not easily recognized morbid mental action. Incalculable mischief would ensue before he would be suspected and before he could be recalled. The application of psychiatry to military life is a suggestion of possible tremendous significance in view of the wars existing in all parts of the world many thousands of miles away from the capitals of civilization.

An "Observation Committee," consisting of an "obese specialist," an "oral surgeon comparative anatomist," other specialists microscopical and macroscopical, some nonspecialists, a member of "la Faculté de Paris," "medical and scientific experts," but especially of "representatives of the medical and daily press of this city," was recently convened in New York City to witness the demonstration of the "improvement made in the last four weeks of 50 consumptive and cancer patients" as the result of some marvelous sort of mystic treatment. "The city editor of the PHILADELPHIA MEDICAL JOURNAL" was also invited to witness, but in medical journalism such an official does not exist, and it is very questionable if his creation would be of advantage in the progress of medical science. We would suggest instead that the medical profession should shake itself together, and through its medical societies put a stop to the abuses so frequently encouraged by city editors. "Observation Committees,"

even if composed of "microscopical presidents" and "obese specialists," are also greatly in need of being observed, and with such rigor that they shall become so very microscopical as to be utterly invisible, and so lean that death shall speedily result.

Progress in Michigan.—In the *St. Paul Medical Journal* for October Dr. Charles Lyman Greene epitomizes the history of the movement against the attempt to regularize and justify the "divvy-of-the-spoils" between general physician and specialist-consultant. Investigation showed the extensive prevalence of the base practice, and in the article by Dr. G. Frank Lydston, published in the PHILADELPHIA MEDICAL JOURNAL, November 4, 1899, it was made manifest to the whole profession. As a result of the crusade instituted by Dr. Greene and his associates the assurance is now given that in Michigan the practice is "virtually killed." Every State and other medical society should take similar action to that of the Minnesota State Medical Society, which in June 28, 1900, by unanimous vote, passed the following resolutions:

"WHEREAS, It has come to the knowledge of this society that the paying and receiving of commissions on cases referred by one practitioner to another is an established custom among a certain small number of physicians, and,

"WHEREAS, We, the members of this society, regard such practice or practices as reprehensible, degrading, unethical, and unprofessional, and believe that their maintenance threatens the very existence of scientific and humane medicine, it is hereby

"Resolved, That the giving or receiving of commissions as above described, after this date, shall be considered as constitutional grounds for expulsion from this society.

"Resolved, That our delegates to the American Medical Association shall be and are hereby requested to use their influence in every possible way to make the above described offense cause for expulsion from the national association."

The Nature of Acute Ascending Paralysis.—Acute ascending paralysis, as described by Landry, is characterized by the development in rapid succession, generally in ascending, rarely in descending, order, of paralysis of the lower and upper extremities, the diaphragm, the bulbar nerves, without sensory disturbances, tenderness, atrophy, electric changes, or involvement of the bladder or the rectum, terminating fatally in a few days or weeks, although rarely ending in recovery. No constant or distinctive lesion is known. There has been not a little discussion as to whether the symptom-complex represents a morbid entity, and

there have not been wanting those who have considered the condition a form of polyneuritis, while others have referred the disturbances to the spinal cord, the medulla, and also the brain. Now, the newer pathology seems to indicate that the same influences that exert deleterious effects upon one part of the nervous system are likewise capable of exerting similar effects upon other and even all parts; and, further, that disturbances in function may result from alterations in nutrition, or in structure even, not discernible by present methods of research. It should, therefore, not be surprising if at times symptoms of peripheral neuritis should be associated with those of poliomyelitis, and both with those of polioencephalitis. There would thus be corresponding variations in the clinical picture, and Landry's paralysis may be looked upon as the expression of one or more of these conditions, separately or in combination.

Surgical Operations upon Neurasthenic Women.

—Not a few of the reported marvelous cures wrought by the various mind-cures are of women who have been recommended to have major surgical operations for the relief of their supposed diseases; some other cases have already been subjected to repeated operations without relief. It is in this manner that the profession reaps the harvest which it has sometimes sown by indiscriminate resort to operative measures when no definite pathologic reason for such operations could be demonstrated. Recently such a neurasthenic woman came under observation who gave a history of seven successive celiotomies by various surgeons for conditions which at this time seem to have been largely simulative. Another woman was seen who had been subjected to five operations on the uterus and had had both kidneys anchored (by different surgeons); the neurasthenic conditions now point to the bladder, and she may yet find some enthusiast rash enough to make a suprapubic or vaginal fistula in that organ, thus adding another to her many miseries. These women may indeed be said to "have suffered many things of many physicians"; nor is it to be wondered at that when such a case, either through lapse of time or the substitution of an overwhelmingly interesting subject for the nervous system, happens to get well, mind-cure or christian science or some other divine afflatus gains great credit, while medicine is put to shame by the deeds that have been enacted in her name.

The Educated Suicide's Brain.—Dr. Burt G. Wilder, than whom no man is more competent to study the fissures and gyres of the human cerebrum, has at various times presented some most interesting observations on high-type brains. A few years ago, for instance, he demonstrated before the American Neurological Association the brain of an educated man who had committed suicide. In this brain Dr. Wilder announced

that he had discovered a duplication of the central fissure—a very rare anomaly and one well worthy of special note. Dr. Wilder, of course, did not claim that there was any relationship between this duplication of the central fissure and the suicide of the man in whom it was found, and he evidently intended nothing more than to point out a coincidence. The inferences, in fact, to be drawn from the case were left to the individual proclivities of the members of the Association, and we have never heard that there was any unanimity among them as to the significance of the case.

We regret now to have to announce that Dr. Wilder, with rare frankness and scientific fervor, has felt impelled to revise his conclusions in this case. At the last meeting of the Association he announced that but two cases of genuine duplication of the central fissure were on record—those of Giacomini and Calori—and that his own enthusiasm had caused him to think that his educated suicide was a third case. He was misled by the wound of exit of the bullet, which had somewhat marred the topography of the left cerebral hemisphere. He comes reluctantly to the conclusion that the fissure was not duplicated but merely interrupted, and that the wounded fissure was not a second central, but merely an unusually long postcentral fissure.

We may be permitted to hope that Dr. Wilder, who is unusually fortunate in being made the legatee of interesting persons who wish to dispose of their brains, will yet find a case of duplication of the central fissure; but we trust it will not be necessary for any illustrious individual to kill himself in order to furnish Dr. Wilder with this coveted prize.

An Emergency Ration for the United States Army.—An interesting experiment is being made in the United States Army in order to determine the value of certain condensed foods or rations for soldiers. The United States Army needs such a ration for the use of troops sent suddenly into a hostile country, beyond a base of supplies, where it would be impossible to forage on the enemy. This ration should occupy a minimum space, sustain the soldier's strength, preserve his health, and be palatable. A board of army officers is now testing several samples of such a food in actual practice in the field. This board has had numerous samples submitted to it, but has selected only three as deserving of a final test. A single ration is intended to keep a man in good condition for 24 hours. It is contained in an air-tight tin box. One of these three rations is prepared by the board itself, and consists of two cakes of sweetened chocolate, and three cakes of a meat and cereal compound. Another, sent from New Jersey, contains a cake of tea leaves and a meat and cereal compound. A third, from Chicago, has tea for a stimulant, and meat-extracts in its food-combination. Each ration has a small quantity of salt and pepper.

The board naturally regards its own ration with greatest favor. The chocolate weighs 4 ounces, and the meat and cereal 4 and 8 ounces respectively, a total of 16 ounces. This ration is contained in an hermetically sealed can, which has rounded edges like a flask and is opened with a key. It may be eaten dry, or cooked in several ways. The board gives the details of its preparation, and claims that it is an ideal ration for an American soldier, who requires both bread and meat, and does not, as a rule, like tea. Chocolate is substituted for coffee, because it may be either eaten as a candy or prepared as a drink, and because coffee, when roasted and ground, soon loses its strength.

These tests are now being made in Southwestern Oklahoma by Capt. Fountain, of the Eighth Cavalry, and Capt. Foster, of the Fifth Cavalry. The trial is being made with 25 troopers in the Comanche reservation, where the conditions are similar to those of real war. Accurate measurements and weights of the men are taken twice a day, and their condition carefully noticed while on the march.

Pain in the Back as a Symptom of Intestinal Disease.—It has long been a lay custom to attribute pain in the back—lumbago—to disease of the kidneys. The old soldier who has an ache in his back makes a claim for pension upon the ground of kidney-disease. Yet, physicians well know that very seldom indeed does a pain in the back indicate renal disease. It is true that pain in the back frequently accompanies renal disease, but cases of lumbago are far more frequent than cases of nephritis. Pain in the back is very frequently rheumatic in its nature, and it is so regarded by physicians in the great majority of instances. It will thus be recognized that this symptom is not characteristic of any special disease. Many times the cause will be found in the secretion by the kidneys of a high-colored concentrated urine, of high specific gravity, or at least urine of this character will be found as an accompanying phenomenon. No doubt in such cases there is a degree of passive congestion of the kidneys, increased by deficient ingestion of water. At least such cases are promptly relieved by prescribing the regular ingestion of definite and considerable amounts of pure water.

There remains a class of cases of lumbago in which the cause is very different, and which is not mentioned in the ordinary writings upon the subject. It is frequently observed that in from four to six hours after the administration of a purgative, the subject has marked aching pain in the small of the back and in the superior gluteal region. So too in diarrhea, dysentery, the choleras, and other conditions which are characterized or accompanied by increased peristaltic movement, there is likely to be usually quite severe back-ache. This pain is of such character as often to seem as if due to a tugging of the mesentery upon its attachment. Certainly it is due to irritation of the fibers of

the cerebrospinal nerves that go to the intestines, from whence the nervous irritation is reflected through the fibers of the cerebrospinal nerves that supply the skin and muscles of the back.

It seems to be usually overlooked that chronic intestinal disease is frequently accompanied by backache. In every case of aching back, in which the physician is unable readily to find a definite cause, careful investigation should be made as to the existence of even a mild grade of intestinal catarrh. Not a few cases of lumbago, which are relieved by the administration of salicylates upon the hypothesis of a rheumatic origin, are really benefited through the antiseptic action of the drug upon the infected gastrointestinal tract. It will readily therefore be seen that the careful physician must constantly be on the lookout for intestinal disease as the cause of backache, for the discovery of such origin will often enable him to bring about a brilliant therapeutic result. This observation is the result of clinical observation. After writing, accident brought to our notice a paper on this subject by Mr. Harding Freeland in the *Lancet* for April 21, 1900. This writer has made similar observations, particularly of sacral pain in cases of rectal disease, such as piles, ulcer, and cancer. He also notes, however, that simple intestinal catarrh gives rise to back-pain, and that he has found speedy relief from ichthyol in doses of from five to ten grains.

Suggestions to Writers: No. 63. Forwarding Manuscripts, Letters, Electrotypes, etc.—There is hardly a week that letters and manuscripts are not received by us without any indication whence they come. The writers either fail to mention the name of the city, State, and street at the head of their letters, or they fail to sign their names to the letters. Manuscripts are sent without a letter enclosed in the package, and the letter intended to be sent separately does not come for some time, or it never comes. There follow in weeks or months, inquiries, remonstrant or angry, as to our lapses of courtesy or our business ability. Altogether such things cause a deal of trouble, unnecessary work, and bad feelings. In one day we have received three sets of electrotypes without a word to tell by whom they were sent, what article they were to illustrate, etc., and with no proofs to show what the pictures represented.

Now, brethren, these things should not be! Have pity on the poor editor! May we not beg correspondents:

1. Never to write a letter without it shows who writes it and where it is written.
2. Never to use an envelope that does not have the address on the corner.
3. Never to send a manuscript without an accompanying note giving at least the address of the sender.
4. Never to roll manuscripts.

5. Always to retain a copy of manuscripts. Copying-ink and copying-paper are inexpensive.

6. In forwarding electrotypes to write on the back of each with a pencil the sender's name; send proofs of the same, if possible; at least designate the article they are to illustrate.

Medical Sermonets, No. 23. Hatred of the Medical Profession.—There are few social phenomena more puzzling and psychologically inexplicable than the blind and furious hatred of so many American citizens for the medical profession and for medical science. One who has not studied the fact has no adequate conception of its extent and intensity. All over the country there are societies, sects, journals, books, and preachers, of every variety, animated by it and giving their lives to it with a rage that is ferocious and unrelenting. The emotion is the very heart of thousands, perhaps millions of otherwise sensible or half-demented people. It is the source of energy of the antivivisectionists and antivaccinationists, of the eddyites, and of the osteopaths, of the antidrugs, and of a hundred antis too complex and numerous to study or even to list. Whence has it come? Why is it so violent? Why does it continue? Will it ever end? What have we done to arouse it? What is our responsibility? How shall it be met?

With the best will in the world to explain the fact, we must confess that historically and sociologically the problem seems to us almost insoluble. As a profession we have no acute consciousness of social sin in our souls, and with the most searching self examination we cannot see that our feeling of guiltlessness is due to any exceptional moral obliquity or subnormal insensitiveness of conscience. Our incomes are not greater than those of other professions, not so great for instance as those of the lawyers, the manufacturers, the ward-bosses, not near so great as those of the lawmakers and law executors, newspaper publishers and editors, and who ever heard a doctor classed as a capitalist? The detestation, therefore, does not come from the same source as the hatred of the rich. We are not plutocrats.

We are not idle parasites of the body politic, because no class works harder, and none gives anything like so large a share of life gratis to hospitals, dispensaries, and private charity-work.

We have no power, not even as much as the antis, for we cannot get the most obvious laws enacted in our favor as a class, and we are hopelessly disunited and disorganized. The bitterness toward us is consequently not of that kind which produces rabid socialism or nihilism. We can compel no one to consult us; hardly any one pays us unless he wishes to do so, even after securing our services; every one is free to buy drugs of unknown powers (many millions of dollars' worth of nostrums are sold every year); or he may consult any one of a thousand types of quacks; or he may die as drugless as he desires.

The only thing in which we seem to have control of the actions of others or their bodies and wills, is in reference to vaccination, and a few vague and ineffective quarantine and hygienic laws. But in these things there is no one who sincerely desires it, alas! who cannot escape the laws, and as only fools deny the contagiousness of disease these "tyrannies" are merely poor devices for self-protection. We have as good a moral right to prevent others from throwing diseases at us as we have to prevent them from firing brickbats or bullets at us, but we have not the legal right.

Perhaps the most constant charge against us, the one that most surely and persistently appears in anti-literature relates to drugs. Antidrugism is the single cry that will rally the greater number of antis to the standard of revolt. In reading the medical books of the middle ages we realize that the protest would then have been valid. The greater the dose, the more complex the prescription; and the more nasty the ingredients, the greater was supposed to be the efficacy. In answer to this it may truthfully be said that the medieval people demanded this sort of therapeutics as much or more than the so-called physicians, and that medical science, properly-speaking, had not arisen. It is to the credit of homeopathy that at one time it helped in the natural reaction against excess in medical therapeutics. But in encouraging the modern hatred, for which it is largely responsible, it exposes itself to three most ludicrous contradictions: First, it perpetuates a filthiness in therapeutics which only medievalism could exceed. We have the trade catalog of a homeopathic drug store in which are enumerated and priced hundreds of loathsome and nauseating products of nature and disease. Second, at its best, and even if the drugs were taken as Hahnemann advised, solely by smelling, and in the most attenuated and mystic potentization, no homeopathist would confess himself an out-and-out antidrug man. Third, an examination of actual modern homeopathic prescriptions at our drug stores shows that, whatever the theory, practically homeopathists often give the same drugs in the same doses as do we.

To the antidruggers it may also and lastly be said that there is no more uncompromising enemy of the nostrum traffic than modern medical science. It is not we who enacted the laws which encourage and protect this traffic; it is not we that spend millions upon millions for patent impotent medicines; it is not of our own free will that we give most of the prescriptions written, but because the popular prejudice demands them. Our danger rather lies in the direction of therapeutic nihilism.

So far as the scorn of us is born of scorn of drugs, it is logical only in so far as it reacts by emphasis and practice of hygiene, of public and private sanitary laws. Do we find such enthusiasm among the antis? Are they the workers in cleaning cities, abating unsanitary nuisances, and extinguishing the thousand breeding places and habits of disease? Not one, not once! These are matters to which they are utterly indifferent,—except sometimes in ungrammatical verbosity and rant springing from morbid egotism and ending in silly gush long before action begins or facts are touched.

It has long been remarked that nihilism born and bred of Continental despotism may emigrate to the United States and here illogically wreak its vengeance on a freedom from tyranny which should be called license, and upon financial and social conditions more favorable to the poor than have ever been known in the history of the world. So it may come about that a hatred of medicine born on the Continent of something akin to medical tyranny or monopoly, often of hospital brutality, may transplant itself to our soil and bloom with an absurd luxuriance, where hospitals advertise for patients and where medical monopoly would be a term as ludicrous as was ever coined by the overworked opera bouffe librettist. Our hospital manners may be sometimes bad, but they hardly generate very violent grudges in patients.

Perplexed by the anomaly, we might suggest that either antireligion, or superstition is to some degree account-

able for the unreasonable antimedical bigotry. At times this seems to throw a ray of light upon the problem, but it soon fades out, and accounts at best for a few individual and sporadic cases, leaving the etiology in a general and adequate sense as obscure as ever.

As a disappointing result it must be admitted that the student of morbid popular psychology has here a subject worthy of his best powers. One seems driven to adopt some temporary and unsatisfactory half-explanation. In all times, but especially in the uncontrolled expansiveness of an unlimited democracy, the illiterate mass of people seem driven to try wild experiments with their minds and with social evolution. Reckless of history and of all past experience they grasp wildly at any theory, fact, or clue, anything that places the blame for their unhappiness anywhere except upon fate and their own ignorance and their own consciences; thus then is got a satisfaction in rage and passion instead of by self-examination and patient adherence to duty.

Our own professional duty certainly remains clear; it is to perfect our conscience and our art; it is to heal disease; these who hate and revile us are diseased,—at least mentally—and we must cure them. We must pity and help them, but our pity must not go so far as to let them infect the innocent, enact their delusions into laws, and wreck the very bases of civilization. Such pity would be inexcusable weakness.

Reviews.

Physiologic Optics. Dioptrics of the Eye, Functions of the Retina, Ocular Movements and Binocular Vision. By DR. M. TSCHERNING, adjutant director of the Laboratory of Ophthalmology at the Sorbonne, Paris. Authorized Translation from the Original French Edition. Specially Revised and Enlarged by the Author. By Carl Weiland, M.D., former Chief of Clinic in the Eye Department of the Jefferson Medical College Hospital of Philadelphia. With 212 Illustrations. Philadelphia: The Keystone, 1900. Price, \$3.50.

The Charybdis and Scylla of the ophthalmologist are on the one hand a too great absorption in the theoretical aspects of his subject, and on the other, a merely mechanical application of the rules of the art in the daily routine of practice. For the student who counts on equipping himself for the career of a specialist in a six weeks' course Tscherning's volume has no interest. For one who hopes to master the abstract principles of his work some day this book is an excellent introduction to the more extended treatises of older writers. That it contains some false theories and false practical deductions is simply saying that like many other works on the eye it was not written under plenary inspiration. We congratulate the author on his American translator, who has disarmed criticism by pointing out in preface and footnotes the main divergences from what is held orthodox here. It is not simply a compilation of classical theories, but an exposition of valuable original research as well. The illustrations are excellent, and the book is published in attractive form.

Cancer of the Uterus, Its Pathology, Symptomatology, and Treatment; also the Pathology of Diseases of the Endometrium. By THOMAS STEPHEN CULLEN, M.B., of Toronto, Associate Professor of Gynecology in the Johns Hopkins University. With eleven Lithographic Plates and over three hundred

colored and black illustrations in the text, by Max Brödel and Hermann Becker. Pp. 693. New York: D. Appleton & Co. 1900.

America has been justly styled the birthplace of gynecology and the specialty has been deeply indebted in the past to American practitioners; but recently the brilliant contributions to gynecologic literature have added new luster and given increased impetus to our national surgical labors. There is no contribution in English, or in any other language, on cancer of the uterus that equals or begins to compare with this work which it is our pleasant task to review. There is no subject of greater import to general practitioners of medicine than the early recognition of malignant disease; there is no disease in which early diagnosis is so important to the patient. Dr. Cullen's work deserves the highest praise and the widest distribution, and we are not lauding it too highly if we term it a life-prolonging and a life-saving volume. The clear and lucid teaching it presents leaves no excuse or hiding place for the perfunctory practitioner who neglects to note the premonitory signs or to institute thorough investigation in cancer of the genital tract. In Dr. Cullen's book, cancer of the uterus, its pathology, symptomatology, diagnosis, and treatment are most accurately described as well as the pathology of diseases of the endometrium. Every gynecologist of experience can appreciate the words of the author in his preface: "That the number of cases of cancer of the genital tract coming too late for operation is so appalling that the surgeon is ever seeking to devise ways and means by which the dread malady may be more generally detected at the earliest possible moment, at a time when complete removal of the malignant tissue is still possible. The general practitioner as a rule is first consulted and upon him largely falls the responsibility of arriving at a timely diagnosis." In this work it has been the aim to give the family physician a clear idea of the early signs of carcinoma, in order that he may always be on his guard and may not treat too lightly any suspicious indications which may be present. Our only criticism is that probably the size of the volume will prevent its wide distribution among general practitioners, while it will most certainly be found in the library of every specialist. If the statement of Williams, that cancer is four times as common as it was 50 years ago, be true, the value of the work will be better estimated. After an introductory note and a chapter devoted to the anatomy of the uterus, a most important section treats of the removal and examination of uterine tissues for diagnostic purposes, the method of obtaining the suspected tissues, examinations of scrapings and technic. The unfortunate consequences that may arise from careless manipulation of tissues are carefully detailed. Nine chapters are then devoted to malignant disease of the cervix, treating of clinical aspects and differential diagnosis of squamous cell carcinoma and adenocarcinoma of that part of the organ. Then the malignancy of the body of the uterus is considered. Clinical histories of many illustrative cases are introduced. Sixteen pages are devoted to deciduoma malignum, presenting an excellent resume of our knowledge of this unusual condition. Dr. Cullen, in summing up the various analyses as to the causation of carcinoma, finds that heredity seems to have little influence; trauma as produced by parturition apparently bears a causal relation to cancer of the cervix, but not to that of the body. Neither the theory of Cohnheim nor that of Ribbert explains its origin, and the weight of evidence is against its parasitic theory. The results of the many investigations, while giving an increased knowledge concerning the histologic structure of carcinoma, have still left its etiology an unsettled question. The possibility of implantation is thus far conceded, that under favorable conditions cells of a new growth may be transferred from one part of the body to another and still continue to grow; and he considers it wise in performing hysterectomy to avoid as far as possible any chance of conveying particles of carcinomatous tissue to the healthy parts. This valuable work concludes with an eloquent appeal for early diagnosis of malignant disease of the uterus. The book is splendidly illustrated with 11 lithographic plates and 300 colored and black illustrations in the text. The fine work of the artists, Brödel and Becker, who added so much to Dr. Kelly's work, is here in evidence. The index is satisfactorily complete and the binding and typography excellent.

Correspondence.

OLD AGE.

By H. C. WOOD, M.D.,
of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

My attention has been strongly attracted by your editorial in the number of November 10th, in which you discuss "Old age" as an official return upon a death-certificate.

Old age is certainly not a disease, and scientifically should never be given as the cause of death. The individual really dies of senile atheroma, or senile nephritis, or senile something else. On the other hand, the theory that old age is connected with a definite number of years is incorrect. Nearly 40 years' experience in the practice of medicine has very firmly convinced me that as the human race has a general period, after which tissue-changes take place resulting in "death from old age," so do not only individuals but families have an allotted time. There are men whose tissues are not as senile when they are 80 years of age as others are at 70, or others at 60, or even at 50 or 40. I have seen the almost complete extinction of 2 generations of certain families by the death from senility of the various members when between 30 and 40 years of age; as the deaths in these cases were the result of changes in the tissues, commonly called "senile," it is just as correct to say that the subjects died of old age, though they were perhaps only 35 years old, as it is to say that certain other persons have died of old age at 75 years of age.

It would be of no improvement in our death-certificates to limit death from old age to a certain period of existence. If there is to be any change from the present plan it should be the abolition of old age as a recognized cause of death, and the requiring that the death-certificate should show that the subject died of senile atheroma or whatever was the cause of the taking off.

It seems to me a matter of very grave importance for the purposes of prognosis and practical treatment, that the medical practitioner should recognize that old age may commence at any time of life. Some of the so-called cases of neurasthenia are in fact only instances of premature senility; hence their hopelessness.

FOREIGN BODIES IN THE URETHRA.

By HERBERT D. JONES, M.D.,
of Decatur, Ill.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

In your journal of the 20th inst., Dr. C. M. Ellis reports a case of "hat-pin in the urethra," and states that only three prior cases have been reported. I can add one to the number; for about four years ago, in this city, I was called by an anxious wife to see her husband, who was about 24 years old, and in that same rather ludicrous predicament. He had a deep-seated stricture and when it became troublesome had paid a surgeon a small fee for the passage of a steel sound. To avoid this expense on subsequent occasions he had used a hat-pin with a glass bead end about the size of an ordinary rifle bullet. Of course, after one or two ventures the inevitable result followed and I was called to his relief.

In efforts for its removal he had caused the point of the pin to become imbedded in the urethral membrane near the

meatus, and finding myself unable to disengage it I pushed it through, embracing as little tissue as possible and reversed and pushed it out as did Dr. Ellis in his case, and no untoward results followed.

I was unaware that the accident or the method of relief were very unusual and hence have never reported it.

Allusion to my patient's false economy, which prompted him to so hazardous an experiment in self-treatment, recalls a more recent case in which a young farmer (in fact as well as slang) from similar pseudoeconomic motives concealed a condition which would have sent most men posthaste to a surgeon. Inquiring to find an explanation of his wife's apparently debilitated condition, I questioned him as to the frequency of their sexual indulgence, and he informed me he had not for over 2 months been capable of performing that function, and could only with great difficulty urinate on account of a stone lodged in the penis.

Assured that no exorbitant charge would be made he submitted to an examination and a separation of the lips of the meatus revealed the object which must indeed have been a source of discomfort. By enlarging the meatus with a slight incision and the use of a small scoop as a vis a tergo, having failed to grasp it with any available forceps, I soon removed a calculus in size and shape a little like an almond kernel. Whether this forced abstinence was productive of increased virility I cannot say, but at the next biennial increase in his household, his good wife presented to him her first twin product.

INGESTION OF ENORMOUS DOSE OF MORPHIN WITH RECOVERY.

By HERBERT R. GOODRICH, M.D.,
of Philadelphia.

Resident Physician, Eastern Penitentiary.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

PERMIT me to present to the readers of the JOURNAL a case which has come to my knowledge, of the ingestion of a surprisingly large quantity of morphin followed by no markedly evil effects and ultimately a complete recovery. The case did not come under my immediate observation, but is related to me by the patient himself—a man of middle age, in good health, who has a fair knowledge of drugs and chemicals, and in whose veracity I have every reason to believe. Some time ago he passed through a period of profound depression incident to business and social reversals, which were so intolerable to him that he attempted to end his life. He had been suffering from insomnia for a few weeks before, and to relieve this would occasionally take morphin combined with atropin, but was by no means an habitual user of the drug. He carried about with him a vial which originally contained 100 tablets of the combination morphin sulfate $\frac{1}{2}$ gr. and atropin sulfate $\frac{1}{150}$ gr. When at the crisis of his depression of mind, in which he determined to end his life, he counted the tablets remaining in the vial and it contained 81. Dissolving these in a small glass of water he drank the whole quantity and lay down upon the bed to a sleep which he supposed would end in his death. He remembers nothing for 48 hours, when he awoke with no worse effects than a condition of deep hebetude and pronounced soreness and pain on attempted motion—from having lain so long in one position. A country physician was called in by the alarmed family at the end of 24 hours of his prolonged sleep. He knew of the patient's period of anxiety and distress and gave the advice to let him alone, as nature was simply assert-

ing herself and demanding rest from an exhausted human body. A friend who saw him in his sleep said the breathing was very slow, somewhat shallow, but quiet.

I have never read of recovery from such an amount of these poisons, which must have been about 20 grains of morphin and $\frac{1}{2}$ grain of atropin. The patient, who knows of the physiologic antagonistic properties of morphin and atropin, attributes his recovery to the fact that they counteracted each other in their effects.

I present the case to you, asking you to estimate its value, solely upon the fact that I know the patient, that he is intelligent, well educated, has a knowledge of drugs and chemistry, and that I believe the statement to be true.

NEW WORD-COINAGES PROPOSED.

By D. RIESMAN, M.D.,

of Philadelphia, Pa.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

THE German language, with its plasticity and unlimited capacity for coining words, possesses numerous expressions, terse and descriptive, of which we have no English equivalent. Thus, there is a word "Verschlimmerung" for which we know no single word in the English language. We have the word "amelioration," corresponding to "Verbesserung;" but for the other there is no single English word. The deficiency can easily be remedied by coining a word that is etymologically analogous to "ameliorate," viz., the word "apeiorate," which might also be written "apejorate." The word is derived from *ad*, to, and *pejor*, a comparative of *malus*, bad, and signifies "worse." The noun would be "apeioration."

There is in the English language, also, no word antithetical to "magnify." The word "minify" is sometimes employed, but is not the exact counterpart of "magnify" nor is correctly formed. "Magnify" comes from the Latin word *magnus*, great, and *facere*, to make. The proper word would be derived from *parvus*, small, and *facere*, and would be "parvify," corresponding to the German word "verkleinern." The noun would be "parvification."

No special excuse is required for the coining of a new scientific term, but considerable temerity is necessary to coin words that shall become part of the vernacular. There is, however, such a distinct need for the two words, that I have taken the liberty to propose their adoption.

GRAPHIC STUDY OF GASTRIC PERISTALSIS.

By CLARENCE QUINAN, M.D.,

of San Francisco, Cal. §

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I HAVE been informed by Dr. John C. Hemmeter, of Baltimore, that the method for the graphic study of gastric peristalsis recently published in this journal is in many respects similar to one proposed by him in 1895.

I have examined the work to which he refers, and find that we have independently employed the same principle.

My method was the result of a research, conducted to a conclusion in ignorance of Doctor Hemmeter's investigations, his work being unknown both to myself and those in whom I confided.

That the results are so like those obtained by him is an interesting coincident. Parallel instances are very common.

THE LOST ART OF PRESCRIPTION-WRITING.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

MAY I be permitted to call attention to a growing evil, which has not only resulted in a lowering of the art of our profession, but has done much to interfere with the prosperity of the doctor? I allude to the species of laziness which nowadays deters a great many physicians from writing original prescriptions, and prompts them to order ready-made, compounded preparations of drugs; to order tablets, etc. The pharmacy is rapidly falling to the level of the paint shop. In this city alone, the sale of tablets (of many kinds) over the counter to any individual who desires them, has reached enormous and dangerous proportions. The list of tablets which one well-known druggist has been obliged by the Government to affix revenue stamps to is entirely too large. Acetanilid and other dangerous drugs under one disguise or another are sold without restraint, as are tablets containing atropin and other alkaloids. Today many people never think of going to a doctor until they have to, and not only buy all the medicines they wish in a cheap form, but prescribe for each other.

I do not care to take your space to point out other evils with which most of us are perfectly familiar, but I hope you will urge your readers to revive the lost art of prescription-writing.

New York, September 14.

A. H.

DIAGNOSIS OF HEART-MURMURS.

By ALFRED GORDON, M.D.,

of Philadelphia.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I WAS very much interested in reading Dr. Abrams' valuable paper on inhibition of the heart as an aid in diagnosis, which appeared in the columns of your JOURNAL September 29. I had the opportunity to apply the rules laid down by the author in inhibiting the action of the heart by irritation of the vagus in 5 cases. Two of them had a suspicious first sound at the apex, which after an inhibition maneuver gave a distinct murmur. The third case had a diastolic murmur at the apex, which became more pronounced during the procedure. The fourth case, which I have under my charge in the Neurological Clinic at the Jefferson College Hospital, has a distinct double aortic murmur and a systolic mitral murmur which is not entirely clear. The inhibition maneuver gave me a pronounced double aortic murmur and disappearance of the mitral murmur. The fifth case gave at two examinations a suspicion of a systolic murmur in a neurasthenic young lady. The blood-count showed 3,500,000 red corpuscles. I was then inclined to think it was a murmur of anemia. As soon as I became familiar with Dr. Abrams' inhibition procedure and applied it in this case, I saw to my surprise and satisfaction that the murmur entirely disappeared.

I believe that Dr. Abrams' method is extremely valuable for diagnosis, especially in obscure cases, and deserves therefore the entire attention of the profession. He advises to use a cushion on the neck and press hard with the chin. I used with equal results a thickly-folded towel, which is very handy in the office. I wish to make also the following remarks: In almost all my cases of mitral lesions, in order to ascertain whether a murmur is present or not, I use the following method. If I place my stethoscope in front of

the neck immediately above the superior border of the sternum, the mitral sounds are transmitted to my ear; a true murmur will be heard there even more distinctly, and any suspicious murmur of the apex will not be heard at all. The subsequent events in my cases proved that whenever a murmur was heard above the sternum, I had to deal with a true mitral lesion. When it was absent above the sternum, but suspiciously present at the apex, a course of an appropriate treatment removed it also from the apex. I submit this to the profession, as a result of two years' observation.

Special Article.

GUNSHOT WOUNDS OF 1898 and 1899.¹

By SURGEON-GENERAL GEORGE M. STERNBERG,

of Washington, D. C.

Of the 4,919 men injured by gunshot during the years 1898 and 1899, 586 were killed and 4,333 were wounded and received into the field and other hospitals. The killed constituted 11.9% of those struck; the wounded, 88.1%. In other words, 1 man was killed for every 7.4 wounded. The Mauser bullet must therefore be regarded as less deadly than the larger missile used during the Civil War. The Medical and Surgical History of the Civil War shows the following casualties:

	KILLED.	WOUNDED.
United States troops	59,860	280,040
Confederate troops	51,425	227,871
Total	111,285	507,911

In percentages the casualties were: Killed, 17.97; wounded, 82.03; or 1 man killed to every 4.56 wounded. The relative proportion of killed was therefore considerably larger during the Civil War than during our recent experiences. It is to be noted also that many of the wounds of the past two years were made by missiles of larger caliber. Of those reported in 1899, 471 were specially stated as having been caused by the Remington bullet of caliber .45. It is safe to say that had the whole number of wounds received been inflicted by the smaller Mauser or Krag-Jorgensen bullet the percentage of immediately fatal wounds would have been materially lessened.

The less deadly character of the injuries inflicted by the modern bullet is manifested also when we exclude the killed and regard only those wounds which came under the care of the surgeons. Of these, during the 2 years, there were 4,333, and 259 of the patients, or 6% of the whole number, died. The corresponding percentage from the records of the Civil War was 14.3. Table C in Part I of the Medical Volume of the Medical and Surgical History of the War of the Rebellion, shows that among the white troops of the army there were borne on the reports of the sick and wounded 230,018 gunshot wounds, of which 32,907, or 14.3%, proved fatal. The marked reduction of the ratio of killed to wounded may be placed to the credit of the small-caliber bullet; but the lessened mortality among the cases which came into hospital may not wholly be attributed to the humane character of the wounds inflicted by this missile. Due credit must be given to the improved surgical methods of the present day. Wounds of any region of the body may be taken in comparison and the result will always be found to show a decided lessening in the percentage of cases ending fatally among those of the past 2 years as compared with those of the Civil War. Take, for instance, gunshot wounds of the femur. During the Civil War surgeons in the field hospitals regarded a fractured femur as a serious menace to life, the danger from which was believed to be materially lessened by an immediate amputation. The field hospital surgical work after a battle consisted in great part of amputations, excisions, and resections. Of 6,576

fractures of the femur, 2,923 cases were treated by primary amputation, 186 by resection, and the remaining 3,467 by conservative or expectant measures, this conservative action being due in many cases to a want of favorable conditions for the performance of primary operations. The limb was promptly amputated in 44.4% of these gunshot fractures. On the other hand, during the past two years, 82 cases of gunshot fracture of the femur were reported, 6 of which were treated by primary amputation and 2 by resection, the remaining 74 cases being treated by conservative methods, not because the conditions were not favorable for the performance of primary operations, but because of a conviction that under present methods of treatment the limb could be preserved without adding materially to the danger to life. The limb was lost through surgical intervention in only 7.3% of the cases.

The smaller frontage of the jacketed Mauser bullet causes it to inflict flesh wounds of a corresponding diameter. Wounds of entrance and exit and the narrow target of the missile favor rapid healing. Infection was but seldom noticed and when present it was almost invariably about the wound of exit, and consisted of a slight slough and a drop or two of pus under a scab. Of the 1,400 wounded recorded in the Surgeon General's office, none died of external hemorrhage, nor was it necessary to ligate a vessel for alarming hemorrhage on the field. In gunshot wounds of the principal joints, clean-cut perforations without fracture were the rule. A remarkable case of lodged ball is that of a private of volunteers, in which the Mauser bullet entered above the left eye and remained lodged 15 months after the injury with no symptoms of paralysis. Penetrating gunshot wounds of the abdomen were very fatal. Clothing or other infectious substances were not generally carried into wounds to cause inflammatory disturbances. The small sectional area of the jacketed bullet of reduced caliber with its polished exterior that offers little opportunity for the lodgment of dirt and the fact that it slightly deforms adds very much to the absence of infection in the wounds which it inflicts. In the examination of gunshot wounds the x-ray has proved of great value and has especially aided in the interpretation of remote effects, such as paralysis, neuritis, loss of function, etc.

Not only limbs but lives were saved by the surgical practice of the past two years. In the 82 gunshot fractures of the femur the upper third was involved in 32, of which 5 were fatal, the middle third in 27, of which 3 were fatal, and the lower third in 23, of which 1 was fatal. The mortality varied from 4.3% of the cases in which the lower third was fractured to 15.6% of the cases in which the upper third was the site of the injury, whereas the corresponding percentages of fatal cases during the Civil War were respectively 42.8 and 49.7. The whole of the lessened mortality in these serious fractures may be credited to the protection given to the wound by the first aid-dressing and to the care exercised in the subsequent aseptic treatment of the fractured limb.

In penetrating wounds of the thorax the rate of mortality fell from 62.6% during the Civil War to 27.8% during the years 1898 and 1899. The Civil War reports show 8,403 cases in which the results were determined; 5,260 deaths occurred among the number. The reports for the later years, as already stated, show 193 cases, of which 55 were fatal.

There were during the Civil War 3,475 penetrating wounds of the abdomen in which the ultimate results were determined; 3,031 of these, or 87.2% of the total, proved fatal. During the years 1898 and 1899 116 cases, 81 fatal, were recorded, the fatal cases constituting 70% of the total. Of 10 cases in which laparotomy was performed 9 were fatal.

The alteration in the percentages of mortality in fractures of the cranium is less marked than in wounds of other parts of the body. Of 4,243 cases of cranial fracture during the Civil War, 2,514, or 59.2%, were fatal. In 1898 and 1899 68 cases were recorded with 37 deaths, the latter forming 54.4% of the whole number.

Registration of Plumbers.—A conference on this subject was held in Birmingham on October 24. Resolutions calling for parliamentary recognition were passed. Two grades of registration are proposed, one for operative plumbers and the other for master plumbers and inspectors. A higher standard of technical knowledge would be required of the latter classes.

¹ Advance abstract from the Annual Report of the Surgeon-General, U. S. Army.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended November 24, 1900:

Tuesday, November 20.—College of Physicians, Section on Ophthalmology.

Wednesday, November 21.—College of Physicians, Section on Otology.

Thursday, November 22.—Pathological Society.

Anthrax.—As the result of being bitten by a fly while handling foreign hides at the Hoytville Tannery recently Michael Bednorick is threatened with death from anthrax. He is in the contagious ward at the Williamsport Hospital.

Record for Antitoxin.—During the past month 33 cases of diphtheria have been reported to the local Board of Health, of Lancaster, and of these but one terminated fatally. The Board attributes this light mortality to the use of antitoxin in every case.

Pennsylvania Sanitarium Company.—Articles of incorporation were filed recently by this company. The objects of the corporation are to treat tuberculosis, and it is proposed to establish an institution at Clifton Heights, Pa. The capital stock is \$50,000, with \$1,000 paid in.

State Hospital for Insane at Norristown.—The cost of maintaining the 2,100 inmates during the past year was \$3.29 each per week. The trustees have asked for one building for males afflicted with tuberculosis, two for nurses and attendants, a pathologic laboratory and a morgue.

Philadelphia Free Hospital for Poor Consumptives.—At a meeting of the board of managers the president's report showed that during the first 6 months of the present fiscal year 116 patients were cared for at an expense of \$4,584.97. The society now has 31 patients under its care.

The Bucks County Medical Society at its regular meeting at Doylestown, November 7, was addressed by Dr. Joseph Price, of Philadelphia, on **pelvic diseases**. The following officers were elected: President, Dr. G. S. Parker; vice-presidents, Drs. J. A. Crewitt and G. M. Grim; secretary and treasurer, Dr. A. F. Myers.

Diphtheria in Woodbury, N. J.—There are seven cases of diphtheria thus far reported, which are said to be of a mild form. Investigation thus far has failed to reveal the source of infection, although it has been reported that the Board of Health had not made proper efforts to quarantine a case. This is denied by the Board of Health.

The Haddock Memorial Orphanage will be opened December 1 at 806 Pine Street, Philadelphia, formerly the residence of Mrs. Daniel Haddock, who in her will left it to be used as an orphanage for children under 3 years of age. She also bequeathed an endowment of \$125,000 for the support of the institution. A training school for nursery maids will be conducted in connection with the orphanage.

Drought May Bring Contagion.—Long-time residents along the Schuylkill say they do not recall a period when the river was so low as at present. Physicians say that unless there are copious rainfalls to wash out the stagnant pools and replenish the smaller streams cities along the river are in grave danger of contagion. The truth of this assertion is evidenced in Reading, where 19 new cases of typhoid fever were reported last week.

At the **Dauphin County Medical Society**, November 6, Dr. Hugh Hamilton presented a paper on the **mosquito's part in spreading malaria**. The paper reviewed the recent investigations in regard to malaria and yellow fever at length, and gave remedies for immediate treatment of the bite and the methods adopted to exterminate the pests in this country, the Indies, and Italy. The different species of mosquitoes and their characteristics were illustrated by charts and drawings.

Plans for the new Jefferson Hospital to be erected at Tenth and Sansom Streets, Philadelphia, are now under consideration by the architect and trustees, who desire to incorporate the most desirable features in the new building. To this end the leading hospitals of Europe have been visited, and suggestions for the members of the College Faculty submitted, and it is expected that the result of this mass of preliminary work will be one of the most complete, convenient, and perfect structures of the kind ever built.

Filters in Schools.—Of the 10 public filter fountains for which contracts were awarded by the Department of Public Safety of Philadelphia, early last summer, 5 have been installed, and the work approved by the Chief Inspector of House Drainage, under whose supervision all the work is being carried out. Work on the remaining 5 was only recently begun. Contracts for the smaller filters to be installed in upward of 237 schoolhouses were divided between the Maignen Company and the United States Filter Company. The appropriation for the whole of the work amounts to \$30,000, and the several contracts closely approximate that sum.

Typhoid in Rural Pennsylvania.—Typhoid fever is raging in the cement region of Pennsylvania, where the malady baffles physicians and sanitarians. In Cementon, Egypt, Seigfrieds, Northampton and Coplay there are 130 cases, and the list is growing. Whole families are down, and the doctors are overworked. There have been but 8 deaths the past week, but the mortality list will be greatly increased, as many critical cases were reported. Health Officer Cawley, of Allentown, has been detailed by the State Board of Health to make an investigation as to the cause of the contagious spread and to take steps to remedy the conditions. It is suspected that the water used in the cement towns is the cause of the trouble.

Visiting Physicians Want to be Paid.—A movement is on foot among physicians officially visiting the public schools of Philadelphia to ask for payment at the rate of \$50 per month for each physician. There are about 200 visiting physicians now acting under appointment of the Board of Education. Those opposed to the movement say that when the visits were first begun it was clearly understood and stated that the services were to be entirely voluntary, so that any effort now made to obtain remuneration might result in the abolition of the visiting staff, contrary to the best interests of the schools and general public. Some argue that the sum named would be exorbitant for the services rendered. At another meeting to be held it is requested that the physicians present reports of the different grades of cases examined by them since their appointment.

Changes in the Philadelphia Hospital.—The hospital staff will be reorganized and enlarged, free clinics in all departments of medicine, surgery, and dentistry will be opened, a new clinical amphitheater will be built. It has been decided to increase the staff of resident physicians from 16 to 19, with an equitable apportionment of such positions among the various medical schools of the city. A school of children's diseases will be established, as will be new bacteriologic and pathologic departments and an x-ray department, all giving opportunities for free clinics. An ambulance service will replace the police-patrol wagons in which patients are at present transported. There are four new dental surgeons on the staff of the hospital: Dr. R. H. Nones, from the Medico-Chirurgical College; Professor M. H. Cryer, University of Pennsylvania; Dr. I. Norman Broomell, Pennsylvania College of Dental Surgery, and Thomas C. Stellwagen, Jr., Philadelphia Dental College.

Camden County Insane Asylum.—In the annual report the superintendent calls attention to an abuse, which, he says, should be remedied. There are in the institution, he says, a number of aged persons who are not vicious, nor destructive, would harm no one nor anything; they have simply grown old and, possibly, a little troublesome to those whom, perhaps, they have reared. Their weakness 30 or 40 years ago would have been termed childishness, and they would have been cared for at home, or on some home supported by philanthropists. An insane asylum is no place for them. Great benefits have been derived through the many recent improvements made by building a large mod-

ern addition and installing a new water system. He recommends several additional improvements, including lighting and refrigerating plants. The present number of inmates in the institution is 184, of whom 41 were admitted during the year, while a like number were discharged. The cost of maintenance was \$2.27 per week per capita.

A Remarkable Display of Nerve.—One of the most remarkable displays of nerve and will power ever witnessed at any of the Reading hospitals was that reported of Allen Wolfskill, the young man who had both of his legs crushed in attempting to jump from a moving freight train on the Reading Railway. In speaking of the accident, he said: "The moment I dropped to the tracks, I felt the wheels passing over my limbs, and that they were gone. I did not faint, but realizing the fact that I would bleed to death unless something was done quickly, I set to work with a view of stopping the flow. I first tied up my right leg with my handkerchief, and while I was doing this a companion who had been more successful in jumping the train than myself came along and let me have his handkerchief and with this I bound up the left limb." He urged the driver to hurry while on the way to the hospital and said if he did not he would take the reins himself. He did not want ether administered so that he might witness the amputation.

Gross Violation of Drug Laws Charged.—Dr. C. T. George, secretary of the State Pharmaceutical Examining Board, says that opposition to the manner in which the Board is enforcing the pharmacy laws is entirely the work of disgruntled druggists who are attempting to escape the penalties imposed by the laws to protect the public against unscrupulous druggists. He says the law in regard to the sale of poisons is violated to a shameful extent, and the ease with which morphin and laudanum can be obtained is alarming. There are about 30% of the druggists in Philadelphia who are doing everything in their power to evade the laws. The reputable druggists of Philadelphia who wish to see the laws enforced are willing to comply with the requirements. One of the Board's inspectors went into an Italian pharmacy in Philadelphia and bought a deadly poison of a young girl, who had to be helped in finding the bottle, and who allowed the inspector to take as much as he wanted of the poison without any prescription and without any question as to the purpose for which it was to be used.

Vital statistics of Philadelphia for the week ended November 10, 1900:

Total mortality	369
CASES.	DEATHS.
Inflammation of appendix 2, brain 6, bronchi 7, kidneys 16, heart 1, liver 2, lungs 37, pericardium 2, peritoneum 5, stomach and bowels 14, knee 1, spine 1	94
Lungs—tuberculosis of 40, abscess of 1, edema 2	43
Heart—diseases of 29, dropsy of 1, fatty degeneration of 3	33
Inanition 16, anemia 2, debility, 6	24
Diphtheria	153 21
Carcinoma of breast 2, bowels 2, kidney 1, pancreas 2, uterus 3, stomach 8, jaw 1, tumor of chest 1	20
Bright's disease 8, uremia 7, diabetes 2	17
Apoplexy 13, paralysis 3	16
Convulsions	13
Casualties	13
Measles	11
Old age	9
Typhoid fever	38 5
Brain—congestion of 2, hemorrhage of 1, softening of 2	5
Septicemia 2, pyemia 1	3
Alcoholism	3
Indigestion	3
Ulceration of stomach	3
Unknown Coroner's cases	3
Whooping-cough	3
Membranous croup	3
Scarlet fever	29 1
Abscess of neck 1, atheroma 1, burns and scalds 2, cyanosis 1, diarrhea 2, disease of spine 2, hernia 1, homicide 1, obstruction of the bowels 2, suicide—shooting 1, syphilis 1, teething 1, tetanus 1, gunshot wound 1	

Pittsburg Academy of Medicine.—At a meeting held October 29, Dr. F. N. MURDOCH reported a case of

achylia gastrica. Dr. J. C. CHRISTY reported a case of **pulmonary tuberculosis** in which an abortion was produced at 6 months, and questioned the propriety of such a procedure. Dr. WILLIAMSON said it could only be justifiable if mother's life was endangered by a continuation of the pregnancy. Dr. J. M. J. McKENNAN read a paper entitled **Some clinical cases, in which he reported 3 cases of acute hallucinatory insanity.** Many of these cases give a history of alcoholism. In the vast majority of them circulatory and nutritional changes in the cortex are responsible for the condition. In endeavoring to correct this, rest, treatment in an institution, and the administration of digitalis has given good results. Thyroid extract has succeeded when digitalis failed. The other cases embraced one of **hysteria**, one of **spurious paralysis agitans** in a woman of 28, and 2 cases of **hypochondriasis**, in each of which a stricture of the urethra was found. In discussion Dr. THEODORE DILLER said he recalled 2 cases of acute hallucinatory and delusional insanity which he had considered paranoia and given a bad prognosis. Both recovered. He had read of acute paranoia, but was in doubt about it. Closing, Dr. McKENNAN said acute hallucinatory insanity is not very common and it does resemble paranoia. There is frequently a stage of hypochondriasis. He has become very cautious in giving a prognosis in any case of insanity, but especially in this class of cases. Has seen some cases which must be classed as paranoia get better. Dr. J. H. WILLIAMSON read a paper on **Some forms of pelvic disease in women—their causes and treatment.** Discussion was participated in by Drs. MOYER, CHRISTY, HECKEL, and MERCER.

NEW YORK.

Bequests to Charity.—By the will of the late Jacob Crouse, of Syracuse, N. Y., \$18,000 is divided among 9 local charities.

The Medical Society of the State of New York will hold its ninety-fifth annual session in Albany, January 29, 30, 31, 1901.

New Emergency Hospital.—A corporation has been formed for the purpose of erecting such an institution at Herkimer, N. Y.

The Austro-Hungarian Hospital of New York City has made application to the State Board of Charities for permission to incorporate.

Plague Laboratory.—The Board of Health of New York City recently awarded a contract for the building of a laboratory for the study of bubonic plague. It will be erected on the Willard Parker Hospital grounds, and will cost \$19,893.

A Prison Hospital for insane convicts has been erected at Dannemora for Clinton Prison. It will be ready for occupancy this month. The building is 300 long by 40 wide and most of the work on it has been done by the convicts. It will relieve the overcrowding at Matteawan Hospital.

The New York Association for Improving the Condition of the Poor appeals for \$60,000 to carry on the work during the coming year. It is dependent entirely upon the public for support. Last year 3,704 families and 881 homeless men and women were aided by the Association.

Society for the Prevention of Cruelty to Children.—Elbridge T. Gerry has resigned as president of this society. His retirement is reported to be due to the long contest with the State Board of Charities, as to the right of the State Department to subject his society, which received an annual appropriation of \$30,000, to the customary inspection. Vernon M. Davis will succeed Mr. Gerry.

Colonies for the Tuberculous.—It is reported that a society is being organized by Dr. A. J. Austen Kelly, of Brooklyn, for the purpose of establishing colonies for tuberculous individuals in northern New York. Something like 5,000 acres of land have been bought in the foothills of the Adirondacks. The purpose is to establish a number of small farms, each with its own house, and the patients will be given light work out of doors when the weather is favorable.

Rabies in New York City.—This disease appears to be on the increase in New York City, and the Health Department will take strong measures to stamp it out. There will be a special laboratory in the Willard Parker Hospital, where experts will be employed to study the treatment of rabies. It is also planned that the Pasteur treatment by the city shall be free to all residents of Greater New York.

The Buffalo Academy of Medicine.—The regular meeting of the Section of Medicine was held at the Academy Rooms, November 13. The following papers were read: A Review of the Modern Surgical and Medical Treatment of Epilepsy, by L. Pierce Craig; Paresis and Cerebral Syphilis, by Arthur W. Hurd; A Case of Aethenic Bulbar Paralysis, by William C. Krauss; and a Report of a Case of Pseudo-Hypertrophic Muscular Paralysis, by Fridolin M. Thoma.

Diphtheria.—The public schools of Lyons have been closed by direction of Health Officer Veeder, to prevent the spread of diphtheria. Within 10 days 2 deaths and 4 malignant cases have been reported. On November 9 several cases of diphtheria were discovered on board the North German Lloyd steamship *Kaiserin Maria Theresia* by the quarantine officials. One death occurred on the voyage. Several of the passengers were sent to North Brother Island.

Dr. Henry D. Noyes, an oculist and physician of high repute in New York, died November 13 of pneumonia, following an attack of bronchitis. Dr. Noyes was born in New York in 1832. He was a graduate of the College of Physicians and Surgeons in 1855, and supplemented his studies there with four years of special work in Berlin. He was visiting surgeon at the New York Eye and Ear Infirmary, and was a member of the Ophthalmic Society, the Academy of Medicine, and the County and State Medical Societies.

Boarding-house for Alcoholics.—Residents of an aristocratic neighborhood in New York have recently been much disturbed by the establishment of a "boarding-house for alcoholics" in the square. They say they heard shrieks at night, were disturbed by ambulances, and were otherwise distressed until they learned the cause, when they protested and were heeded. It is said the plan of the proprietor of the boarding-house, who was a physician, was not to cure his patients, but to keep them sober—"to keep them from losing their jobs," as he expressed it.

Death of a Leper.—Lee Hing, one of the 4 Chinese lepers who were isolated on Ricker's Island in 1893, died at the almshouse in New York on November 3. At one time they all escaped, but were soon captured and returned to the island. By a decision of Health Commissioner Cyrus Edson, made after a consultation with prominent dermatologists, to the effect that leprosy is not a contagious disease in this climate, the 4 were at one time set at liberty. Lee Hing returned to his friends in Mott street, New York, but finding that he was practically ostracised, he applied to the city authorities to be taken care of. He was then sent to the almshouse, where he lived and finally died in a small isolated building set apart for his use.

Physician's Claim for Services in County Where He is Not Registered.—In an action brought by Michele Accetta against Teresa Zupa, of New York, it was lately held by the Second Appellate Division that a physician who has been regularly licensed by the Regents of the University of the State of New York cannot recover for professional services rendered by him, unless his license has been registered in the office of the clerk of the county in which the services were rendered, as required by section 149 of the Public Health Law which, in the absence of such registration, forbids him to practise in that county, it being made a misdemeanor. The plaintiff proved that he was a graduate in medicine of the University of Naples, and had been licensed by the Regents in 1896.

Camphor Produced by a Worm.—The discovery has been made recently that camphor, which has been known hitherto only as a vegetable product or made synthetically by chemists, is produced by a small animal slightly resembling a worm, though having a number of feet, and known as a diplopod with the scientific name of *polzonium rosabium*. The animal is found in Ontario County, New York, and upon

careful examination it has been ascertained that the substance which gives the odor of camphor is a milky fluid which is exuded from the dorsal pores. This liquid, in addition to possessing the odor of camphor, also has a similar taste. The study of the camphor worm which forms the subject of a paper in a recent issue of *Science*, presents many interesting chemic and biologic problems.

The Tuberculosis Hospital Site.—According to the *Medical Record* the efforts by the residents of Clinton County, New York, to induce the State authorities to erect the proposed hospital for the treatment of incipient tuberculosis at Dannemora, and their opposition to a site at Lake Clear, have aroused the residents of the Saranac Lake region to vigorous protest. At a recent meeting resolutions were adopted and ordered to be forwarded to the State board of health and the forest preserve board, by whom the site is to be selected. These resolutions indorse the selection of the Lake Clear site and condemn that of Dannemora. They object to the latter on the ground that "the surroundings in a penal colony are incompatible with cheerfulness" and "have a tendency to produce melancholia, a condition most to be avoided in tuberculous patients." They also object to the employment of convict labor, which would be used in the construction of the buildings if the latter were erected at Dannemora.

Loomis Sanitarium for Consumptives.—At a recent meeting of the board of managers of this institution, at Liberty Heights, Liberty, N. Y., it was decided to increase the charitable work in connection with the institution, and that the present sanitarium should be known as the Self-supporting Division; the new plant to be erected to be known as the Charitable Division. Ever since the sanitarium was started, there have been a limited number of free patients provided for, and a few have always been carried at greatly reduced rates, but the managers have not been able to meet the great demand made upon them by people of very limited or no means, for free treatment. It is their purpose, at first, to have the Charitable Division accommodate 22 patients, and the rates are not to exceed \$5.00 a week per capita; this rate will include board, lodging, and medical attendance. They also guarantee to make a certain number of these original 22 beds free each year, and within 5 years to have the whole number free. Additions to the Charitable Division will, of course, be made from time to time, and the rates charged will in no instance exceed \$5.00 a week, and as many free beds will be established each year as possible. The Charitable Division will be located about half a mile distant from the Self-supporting Division, but they will be managed under a single administration. The Medical Board heartily endorsed the action of the managers, promising them all possible support. During the 4 years of existence of the Self-supporting Division, this sanitarium has grown from 5 to 21 buildings, and from a capacity of 12 to 125 patients, and is still growing.

The Craig Colony Prize for Original Research in Epilepsy.—Dr. Frederick Peterson, president of the Board of Managers of the Craig Colony for Epileptics, at Sonyea, N. Y., offers a prize of \$200 for the best original unpublished contribution to the pathology and treatment of epilepsy. The prize is open to universal competition. All papers received will be submitted to a committee, consisting of 3 members of the New York Neurological Society, and the award will be made upon its recommendation at the annual meeting of the Board of Managers of the Craig Colony, October 8, 1901. Manuscripts should be sent to Dr. Frederick Peterson, 4 West Fiftieth Street, New York City, on or before September 30, 1901. The successful essay becomes the property of the Craig Colony and will be published in its annual report.

The committee of the Craig Colony Prize for Original Research in Epilepsy for the year 1900, reports that it cannot recommend that the prize be awarded. This year but one essay was submitted. In view of its failure for 2 successive years to recommend the awarding of the prize, the committee feels called upon to state what, in its opinion, is necessary for an essay to be considered deserving.

By the terms governing the competition, original research is a primary requisite. Research as to the pathologic anatomy, the chemistry, the symptomatology, the causation,

the treatment, or the nature of epilepsy, as to the position occupied by epilepsy in regard to social economics—or, in short, anything which will advance our knowledge of the disease, is what the prize calls for. It is, of course, necessary that the facts advanced be presented in a way to convince an unbiased critic of their accuracy, and that the conclusions drawn be justified by the facts. No essay submitted either this year or last year has attained this standard. In view of the fertility of the field, of the constantly increasing number of investigators, and of the present perfected facilities of research, the committee believes that the prize having failed to attract more meritorious contributions is to be explained by its not having been sufficiently called to the attention of original workers.

NEW ENGLAND.

Appointment of Dr. Schaper.—Dr. Alfred Schaper has been appointed to a professorship of anatomy at Breslau, Germany. He was formerly assistant professor of histology at the Harvard Medical College.

Congressman Charles A. Boutelle, of Maine, is still at the McLean Asylum in Waverly. He has been at the hospital several months. There is little probability of his taking his seat in Congress next month.

Yale University.—By the will of Prof. James Campbell of the medical faculty, the university has received a bequest of \$700 to maintain the senior prize, known as the Campbell gold medal, for which he had annually provided since 1888.

Dangers of the Telephone.—The Health Department in Boston has completed a bacteriologic test of public telephones and advises care to avoid actual contact of the lips with the transmitter. Cleansing with a 5% carbolic-acid solution after each use is recommended.

Beriberi Victims to be Sent to Calcutta.—Of the 4 Hindus who have been under treatment at the Boston City Hospital for this disease, 1 has died and the other 3 have been sent to New York by the British Consul, whence they will be sent home to Calcutta. They came to Boston some weeks ago in the British steamer *Arara*.

Suit for Change in Complexion.—A lady of Bristol, Conn., has brought suit against a physician of New Haven for \$10,000 damages, alleging that her complexion has been changed from blond to brunet by the excessive doses of calomel prescribed for her by the physician. The doctor denies this charge and ascribes the change of her skin and hair to the bronze shade to lead poisoning due to handling type while engaged as a typesetter. The case will soon be tried in Waterbury.

Textbooks May Carry Disease.—In a contribution to the columns of the Boston *Evening Transcript* doubt is thrown on the wisdom of the policy of furnishing free textbooks in the public schools. The objection is the danger of the communication of disease. Books pass from pupil to pupil, year after year, without disinfecting, as long as they hold together, and in many cases they must be unwholesome. Many public libraries disinfect books as they are returned to the library, and certainly the need of disinfecting the more-used school-books is greater. That would meet the sanitary criticism of the free textbook system.

CHICAGO AND WESTERN STATES.

An epidemic of diphtheria exists at East Alton, Ill., which has necessitated the closing of the public schools. The origin is not known, but the disease has spread rapidly.

Hershey Hospital.—Miss Mira Hershey, daughter of the late millionaire lumberman, Benjamin Hershey, has purchased ground for the site of the public hospital which she will erect and donate to the city of Muscatine, Iowa.

The Wisconsin State Board of Agriculture will ask the State Legislature to create a sanitary commission to deal with contagious diseases among cattle, and especially to take measures to prevent the spread of tuberculosis.

High Birth-Rate.—The births in Milwaukee County, Wis., by the last annual report, exceed the deaths by 6,000, there being 16,494 births, while the deaths numbered 10,550. This indicates a remarkable natural increase in population.

Plague in San Francisco.—From Angel Island, Cal., are reported 2 deaths from plague. The mother, a Chinese woman, femoral bubo; child, probably pneumonic. The typical organism has been found in each case. The house has had bad sanitary history.

The Denver and Arapahoe Medical Society met, November 13, at Brown Palace Hotel, Denver. An address was made by Dr. W. A. Jayne on the **Diagnosis of tubal disease**, and a paper was read by Dr. C. D. Spivak, entitled **The cestodes**, with report of cases and microscopic exhibition of specimens.

The Arkansas Insane.—Superintendent P. O. Hooper, of the Arkansas State Lunatic Asylum, has completed an investigation, which shows that there is an average of 6 insane persons in each county throughout the State, or 450 in all, unable to secure admission on account of the crowded condition of the institution.

Smallpox in Wyoming.—The Indian Bureau has received a telegram from the Shoshone Agency, in Wyoming, announcing that smallpox has broken out at Lander, near the Indian reservation. Vaccine virus for 1,700 persons, which the agent asks to have dispatched him immediately, has been forwarded. The disease also prevails in Wichita, Kansas, 20 cases having been reported in less than a week, and placed in a detention hospital.

Poor Eyesight in Chicago Schools.—From a total of nearly 5,000 tests made of pupils in the public schools of Chicago it has been learned that in the case of 32% of the boys and 37% of the girls, the keenness of eyesight is less than two-thirds of normal. It is further found that among dull and refractory pupils the percentage having poor eyesight is even larger. The conclusion is drawn that defective eyesight is the cause of the dullness in many cases, and is even responsible for pupils being declared incorrigible.

The Jewish Hospital for Consumptives at Denver, Col., claims to be the only institution in the world where tubercular and pulmonary diseases are treated gratis. The hospital—buildings, equipment and ground—cost about \$50,000 and the yearly expenses are about \$20,000. A wing will be added soon at a cost of \$30,000. The trustees of this hospital met at Cincinnati, November 11, and perfected a permanent organization. There are 35 members and heretofore they have had only a provisional organization.

A City's Right to Establish Pest-Houses.—Owners of land near the smallpox hospital, which was opened in 1896 on Lawndale Avenue, Chicago, recently brought suit against the city to recover damages alleged to have been sustained by their property in consequence of the proximity of this hospital. It was not asserted that it was any more of a nuisance than such an institution must be of necessity nor that the city had been negligent in the care of the hospital. The supreme court held that there is no difference in principle between the right of a municipality to establish a pest-house and its right to build a jail or fire-engine house.

Millers for Pure Food.—The board of managers of the Millers' National Association, which met in Chicago, November 8, took important action regarding adulterants used in the product of mills. The board decided, so far as its power goes, to throw out of the market ground clay, sawdust, ground corncobs and other adulterants that are being at present extensively used in the various kinds of feed and milling stuffs now on the market, greatly to the detriment of the legitimate trade. A copyrighted label, under bond, will be issued by the National Association for the use of its members, and a fine of \$500 will be imposed on any member who is discovered and convicted of misusing this label by placing it on anything but the pure product.

The Visiting-Nurse Association of Chicago has recently been granted a charter. The object is to furnish trained nurses to those otherwise unable to secure skilled attendance in time of illness, and to teach cleanliness and

the proper care of the sick. During the first year there were only 4 nurses in employ and 771 cases were cared for. This is the eleventh year of the Association's life, 14 nurses are in employ and more than 500 cases a month are cared for. A corps of 20 untrained or emergency nurses, who work under the supervision of the doctor and visiting-nurse, has proved of untold value to hundreds of cases where the daily visit of the visiting-nurse is not sufficient for the proper care of the case.

Chicago's Drainage Canal.—Chicago has officially tendered its \$34,000,000 drainage channel to the United States Government. The memorial contains a direct tender from the sanitary district of the channel to the general Government under the terms of the sanitary district law of Illinois, which contains a clause reading as follows: "When such channel shall be completed and the water turned therein, to the amount of 300,000 cubic feet of water per minute, the same is hereby declared a navigable stream, and whenever the general Government shall improve the Desplaines and Illinois rivers for navigation, to connect with this channel, said general Government shall have full control over the same for navigation purposes, but not to interfere with its control for sanitary or drainage purposes."

SOUTHERN STATES.

Tulane Medical School, of New Orleans, which in 1893 increased its course from two to three years, has this year adopted the four years' course. The number of students is also increased.

To Examine Children's Teeth.—A movement has been started in the Maryland State Dental Association which may lead to the examination of the teeth of children in the public schools of Baltimore.

"The Phagocyte."—Volume I, No. 1, November, 1900, recently reached us. It is published monthly in the interests of the students and alumni of the Medical Department of Tulane University, at New Orleans, La.

Richmond (Va.) News.—The movement started some time ago to erect a monument to the late Hunter McGuire has taken definite shape, and the citizens generally are responding liberally. Not only are the various committees actively at work, but such organizations as Lee Camp, C. V., have given liberally. It is now proposed to raise \$10,000 and erect a bronze statue in one of the public parks. Typhoid fever still seems to hold its own; out of 48 cases reported in October, there were 15 deaths.

A New Medical Association.—Invitations have been issued by a committee of the El Paso County (Texas) Medical Society to the members of the regular profession of Texas, New Mexico, Arizona, and Mexico to meet in El Paso on January 17, 1190, for the purpose of organizing a territorial medical association. Volunteer papers are requested from all who are willing to contribute. The names and titles of papers should be submitted early that the program may be completed and sent out in due time. The members of the committee are Drs. I. T. Turner, W. N. Vilas, and F. W. Gallagher.

Smallpox in West Virginia and Maryland.—A negro from a Harrison County railroad camp, where the quarantine was recently raised, has been sent to the Municipal Hospital at Wheeling, W. Va. For 4 days, while suffering from smallpox, he has been in the negro colony. An order for everybody to vaccinate has been issued by the health officers. Several cases are reported in Prince George's County, Md. The cases at College Park are near the Maryland Agricultural College. Every precaution has been taken at the college to prevent further spread of the disease. All the students have been vaccinated and Dr. Fulton, of the State Board of Health, does not think there is any danger of smallpox invading the institution.

CANADA.

Toronto University.—Dr. J. J. MacKenzie, formerly lecturer in bacteriology, has been appointed professor of pathology in succession to Dr. John Caven. The faculty is

spending several thousand dollars on the equipment of this department and it is to be thoroughly organized and brought up to date.

A Literary Research Society has been formed at McGill University. It is presided over by Dr. Wesley Mills, professor of physiology, and is intended to keep its members posted in all the recent advances and researches in the various departments of medicine. Abstracts of papers and studies are given by several members each evening and there is a short discussion.

Sanatorium for the Tuberculous.—This much-talked-of institution has at last assumed a tangible form. A small building has been acquired in one of the suburbs of the city of Toronto and 9 beds are now in operation. Part of the cost is being defrayed by the city and part from patients' fees. It is hoped by this means to meet all expenditures and in time it is expected that the institution will grow and become self-supporting.

Medical Defence.—This subject is now beginning to be a live one in Canada. Several cases of attempted blackmail directed against surgeons have come up in the past year or two, and the profession at large is beginning to realize the danger. Dr. R. Powell, in his presidential address at the Canadian Medical Association meeting at Ottawa this year, drew attention to the subject, and a committee was appointed to report at the next meeting, to be held in Winnipeg.

The Montreal Medico-Chirurgical Society met October 21, Dr. J. W. Stirling in the chair. Two cases of **Cesarean section** were described by Drs. W. Gardner and F. L. Lockart. Both cases did well, mother and child in each case being saved. The reason for operation in one case was a fibroid in the pelvis originating from the cervix uteri, in the other for disproportion between the pelvic outlet and the child's head.

Dr. J. W. Elder showed a boy aged 12, with **carcinoma of the cervical glands**. These were much enlarged but not slender. The boy was rapidly emaciating. The primary growth was situated in the vault of the pharynx. Considerable interest and discussion was elicited over a plan to acquire a permanent home for the Society, and the indications are that shortly such will be provided.

Montreal Milk-Supply.—Much interest has been elicited in Montreal lately over the question of obtaining a purer milk-supply. In common with most large cities in America, the infantile death-rate is very high. This is largely due to ignorance on the part of parents, but also to a deficient and badly inspected and controlled milk-supply. The Montreal Medico-Chirurgical Society have taken up the matter and have ventilated the subject in the public press. They have drawn up a series of rules for the guidance of milkmen and purpose to establish a proper board of control. Dr. R. F. Ruthan is consulting chemist and Drs. Wyatt Johnston and J. Allan Williams are the bacteriologists. The herds will be tested and the dairies examined from time to time. Those milkmen who conform to the regulations of the society will receive certificates to that effect. Already 2 large milk-farms have combined and are erecting commodious premises. No doubt the movement will result in a better milk-supply. At least it will indicate to the general public when they may obtain pure and uncontaminated milk. As the arrangement is a purely voluntary one between the Medico-Chirurgical Society and the dealers, it is likely that the benefits will be only partial, and probably the poorer classes who need protection most will be the least likely to get it. Still it is a sign of progress and no doubt will in time lead to greater results.

McGill University.—The winter session in medicine at McGill University, Montreal, began the last week in September and the classes are larger than ever, about 123 being enrolled in the first year and 461 in all classes. Some difficulty is being experienced in dealing with the larger classes inasmuch as the space for teaching purposes is more restricted this year than usual, owing to the building operations which are now being prosecuted. Extensive improvements in the buildings are being projected, involving the completion of the present irregular mass of buildings into one compact and harmonious mass. The chemical and

pathological departments are now under way and it is hoped they may be ready for use by Christmas. The total improvements look to the increase in the space for the library, museum and a larger dissecting room. In order to interfere as little as possible with the work of the year the contemplated changes will be spread over the period of 2 years. The present capacity of the buildings will be more than doubled when the operations are complete. This great advance was made possible through the munificence of the chancellor of the university, Lord Heathcote, and his daughter, the Hon. Mrs. Howard, who donated \$100,000 for the purpose. It is pleasant to note a great increase in the scientific spirit among the students at McGill this year. An experiment was tried during the summer of appointing certain of the senior class to the position of externe assistants at the outdoor and clinics of the various city hospitals, besides assistants in the departments of pathology, neuropathology, and bacteriology. The result was very gratifying and much good work was done.

MISCELLANY.

Famine in a Province of Mexico.—There is great suffering in the Higuera district, State of Sinaloa, on account of the crop failures and prolonged drought, and hundreds of people are reported on the verge of starvation. Many of them are living on roots of mountain shrubs.

Monitors Unhealthful.—Owing to their peculiar construction the monitors are notoriously unhealthful, and the Navy Department has adopted the policy of relieving officers and men on them at short intervals. The vessels are particularly uncomfortable places of habitation in warm climates.

Dr. Manuel S. Yglesias, health officer of Vera Cruz, Mexico, recently visited the State Quarantine Station at Marcus Hook. Dr. Yglesias came to the United States as a delegate from Mexico to the American Public Health Association at Indianapolis. Since the meeting he has been investigating matters in this country.

Obituary.—STANLEY M. STUART, at Santa Cruz, Luzon, November 6.—JAMES P. CLEAVER, of Philadelphia, at Lakewood, N. J., November 8.—J. S. WALTERS, of Pittsburg, aged 51.—WILLIAM MARSHALL, of Milford, Delaware, November 10.—WILLIAM T. COLLINS, of Camden, N. J., November 10, aged 71.—J. G. WELTMER, of Lititz, Pa., November 10, aged 55.

A Remedy for Rheumatism.—It is said that throughout all Spanish-speaking America a belief prevails that the small hairless dog, familiarly known as the "pelon" dog, can cure rheumatism, and that it is quite common for people afflicted with this disease, living in Cuba, Central America, and Mexico, to keep one or more of the animals in bed, the theory being that the malady passes from the man to the dog.

Test of Khaki Colors.—An interesting and important test is in progress at Fort Myer, Va. Some complaints have been received at the War Department that the shade of garment known as khaki color offers more of a target than blue, which was the color of the former shirts issued by the quartermaster's department. The test at Fort Myer is for the purpose of ascertaining the relative protection offered by the 2 colors. The tests include observations of garments of different colors at various distances.

Disease Among Alaskan Natives.—Officers of the United States revenue cutter *Richard Rush* report that the Aleutian Island Indians, as well as those of the Alaskan peninsula and mainland, are dying off at an alarming rate. The *Rush* was engaged during the summer in Indian census enumeration. Attu Island, in past years densely populated with Alaskan natives, contains only 73 persons, and Atka, the largest island of the group, has an Indian population of but 173. This island half a century ago supported a great tribe. During the past season measles and pneumonia carried off the Indians by the score, and should these diseases become epidemic again next year, the archipelago will become almost depopulated.

Rubber Heels for the Army.—The soldiers of the army will not possess the luxury of rubber heels on the shoes which are furnished them by the quartermaster's department. Some consideration has been given to the subject and it is found that while this equipment possesses merit, it is not practicable to issue rubber heels to the army. The detachment of the heel from shoes of soldiers who are at remote points from the base of supplies would cause a great deal of inconvenience. It is found impossible to replenish such missing articles without much trouble. The idea has, therefore, been abandoned.

Inspection of Cattle.—Dr. T. A. Geddes, Chief of the Miscellaneous Division of the Bureau of Animal Industry of the United States Department of Agriculture, has been detailed as a special inspector, and ordered to Great Britain to inspect cattle intended for importation into the United States. Dr. Geddes will make his headquarters in London, and will go to such parts of the United Kingdom as may be required for examination of animals before shipment. The increasing prevalence of contagious diseases, and particularly of tuberculosis, has made this action necessary for the protection of the animal industry of this country.

Yellow Fever.—Surgeon A. H. Glennan, chief quarantine officer for the island of Cuba, has made a report to the Treasury Department on the yellow-fever situation in Havana. He says that the number of cases decreased in the last week of October, and that there were only 13 deaths in that week. He quotes Major W. C. Gorgas, United States Army, chief sanitary officer, as saying that, notwithstanding the general distribution of the disease, infecting localities not heretofore infected, and the large number of people attacked, an epidemic condition does not exist, and that such a situation in Havana is impossible. He says that from June 1 to October 19, there were 789 cases officially recorded; that the official maps of the city show that there are 857 square blocks in the city, and of this number 525 square blocks have had no cases at all. In a population of 242,000, the average in Havana in October was 10 new cases of yellow fever a day. It is reported that General Wood has informed all the representatives of the steamship firms in Havana that if yellow fever does not abate the medical congress which is to be held in Havana will be transferred elsewhere. The presence of the disease may prevent many tourists from visiting the island. Recently 2 cases of yellow fever have been reported at Natchez, Miss., with 1 death. A surgeon of the United States Marine-Hospital Service is now in the city endeavoring to trace the source of the infection. On account of the lateness of the season no serious epidemic is apprehended. Surgeon-Major Reed and a board of experts will continue the investigation concerning the propagation of yellow fever by mosquitos, and an experimental station will be established outside Havana.

Sickness in the Philippines.—General Bates, commanding the department of Southern Luzon, in his annual report says that the duties of the medical department have been ably performed under many adverse circumstances. The various posts are all supplied with hospitals, and 2 large base hospitals have been established, one at Bacoor and the other at Calamba, to which serious cases are sent for such treatment as may not be available at the post hospitals. Careful and constant attention has been given to the hygienic conditions at the different posts, and especial care has been devoted to the matter of food and pure drinking water. Of the prevailing diseases the most serious are malarial fevers and dysentery. On July 31 the sick report of the department, not including reports from the more isolated posts, show a total of 1,863 men sick. Though this is about 18% of the strength of the command from which reports have been received, it is to be remembered that the conditions of the climate and the nature of the duties performed by the troops are such that a small sick report cannot reasonably be expected. He says that the size of the medical corps of this department is insufficient, there being 18 posts without medical officers, 8 of which stations are without hospital stewards or even privates of the hospital corps. There are in round numbers 2,000 men without adequate medical attendance and of this number 1,000 men are without medical attendance at all. "This condition of affairs is in no wise due to the chief surgeon of this department, who has brought the

matter to my attention and to the attention of the chief surgeon of the division and who has labored zealously, intelligently and unremittingly to obtain the best results with the limited personnel at his disposal. The matter cannot be remedied until a sufficient number of medical officers is sent out from the States."

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Marine-Hospital Service, during the week ended November 9, 1900:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.

Changes in the Medical Corps of the U. S. Army, for the week ended November 10, 1900:

WAKEMAN, Major WILLIAM J., surgeon, is relieved from duty at the First Reserve Hospital, this city, and will report to the commanding general, department of Northern Luzon, for assignment to duty.

EDGER, JR., First Lieutenant B. J., assistant surgeon, will report before retiring board for examination.

WOODSON, Captain R. S., assistant surgeon, is granted leave of absence for 1 month, on surgeon's certificate, with permission to visit Japan.

LEWIS, Captain W. F., assistant surgeon, is relieved from duty as member of examining board.

SCHREINER, First Lieutenant E. R., assistant surgeon, is relieved from duty as member of examining board.

WILSON, First Lieutenant J. S., assistant surgeon, is detailed as member of examining board.

FOAN, First Lieutenant C. S., assistant surgeon, is detailed as member of examining board.

CALVERT, First Lieutenant W. J., assistant surgeon, will proceed to Hong Kong to study the bubonic plague.

NICHOLSON, JOHN L., acting assistant surgeon, is relieved from temporary duty at the Army general hospital, Presidio of San Francisco, and assigned to and will report for temporary duty on the transport "Port Stephens" during the voyage of that vessel to the Philippine Islands. Upon arrival at Manila he will report for assignment to duty.

NEWLOVE, GEORGE, acting assistant surgeon, is granted 3 days' extension of his 7 days' leave of absence.

ASHBURN, First Lieutenant PERCY M., assistant surgeon, is relieved from temporary duty at the Army general hospital, Presidio of San Francisco, and assigned to and will report for temporary duty with troops on the Army transport "Sherman." Upon arrival at Manila he will report for assignment to duty.

BARRY, EDMUND, acting assistant surgeon, is relieved from temporary duty at the Army general hospital, Presidio of San Francisco, and assigned to and will report for temporary duty with troops on the Army transport "Sherman." Upon arrival at Manila he will report for assignment to duty.

CARR, Major LAWRENCE C., surgeon, U. S. Volunteers, chief surgeon, department of Eastern Cuba, is relieved from further duty in the division of Cuba, and will repair to this city and report to the Surgeon-General for instructions.

WOLFE, First Lieutenant EDWIN P., assistant surgeon, is relieved from further duty in the department of Eastern Cuba, and will proceed to Fort Hamilton, N. Y., and report for duty.

BROOKS, WILLIAM H., acting assistant surgeon, is relieved from duty at Fort Hamilton, and will proceed to San Francisco, and report for duty with troops destined for the Philippines, and upon arrival at Manila will report for duty.

TURNER, SAMUEL S., acting assistant surgeon, is relieved from duty at the recruiting office, Chicago, and will proceed to Fort Sheridan, Illinois, and report for duty to relieve Acting Assistant Surgeon Walter Whitney.

WHITNEY, WALTER, acting assistant surgeon, will proceed to Fort Walla Walla, Wash., and report for duty to relieve Acting Assistant Surgeon John E. Bingham.

BINGHAM, JOHN E., acting assistant surgeon, will report for annulment of contract.

WINN, First Lieutenant ROBERT N., assistant surgeon, is granted leave of absence from November 1 to November 30, inclusive. Upon expiration of his leave he will proceed to Fort Riley, Kans., and report for duty.

WARREN, STANLEY S., acting assistant surgeon, is granted leave of absence for 1 month.

LONGINO, THOMAS C., acting assistant surgeon, now on duty at Fort Sam Houston, will proceed to Fort Clark, Tex., and report for duty during the absence of Acting Assistant Surgeon Stanley S. Warren.

SHAFFER, J. J., acting assistant surgeon, is granted leave of absence for 1 month.

BARNEY, CHARLES N., acting assistant surgeon, will proceed from Fort Monroe, Va., to Fort Dade, Fla., and report for temporary duty during the absence of Acting Assistant Surgeon Shafer, and upon completion of duty will return to his station.

KEAN, Major JEFFERSON R., surgeon, U. S. Volunteers, par. 12, S. O. 256, October 31, this office, relating to, is revoked.

NEUGARDEN, Captain GEORGE J., assistant surgeon, par. 12, S. O. 256, October 31, this office, relating to, is revoked.

CARTER, JR., HENRY R., acting assistant surgeon, orders of August 31 relating to, are revoked and he is relieved from temporary duty at Seattle and will proceed to Vancouver Barracks for duty.

MCCALL, JAMES H., acting assistant surgeon, is granted leave of absence for 1 month and 15 days from December 1.

BROOKS, WILLIAM H., acting assistant surgeon, upon being relieved from duty at Fort Hamilton, will proceed to Fort Schuyler in time to report in person to the commanding officer at that post on December 1 for temporary duty, and upon completion of this duty will comply with the instructions in orders of November 2.

NORMAN Major SEATON, surgeon, Volunteers, recently appointed (from captain and assistant surgeon, Thirty-ninth Volunteer Infantry), with rank from October 30, is assigned to the Thirty-ninth Infantry.

BRESON, Captain EDWARD G., assistant surgeon, Volunteers, recently appointed (from first lieutenant and assistant surgeon, Thirty-ninth Volunteer Infantry), with rank from October 30, 1900, is assigned to the Thirty-ninth Infantry.

BREWER, Captain ISAAC W., assistant surgeon, Volunteers, recently appointed (from first lieutenant and assistant surgeon, Thirty-sixth Infantry, U. S. Volunteers), with rank from October 12, 1900, is assigned to the Thirty-sixth Infantry.

A board of medical officers, to consist of Lieutenant-Colonel BENJAMIN F. POPE, deputy surgeon-general; Lieutenant-Colonel A. C. GIRARD, deputy surgeon-general; Major S. O. L. PORTER, surgeon, U. S. Volunteers, is appointed to meet at the Army general hospital, Presidio of San Francisco, October 29, to examine into and re-

port upon the present physical condition of Captain JOHN A. PERRY, Thirteenth Infantry, now at the Presidio of San Francisco.

The following named medical officers and acting assistant surgeons, U. S. Army, are relieved from duty at their present stations, and will report to the commanding officer, transport "Meade," to leave for San Francisco, Cal., for duty on vessel en route, reporting upon arrival to the commanding general, department of California, as indicated: Major HENRY D. THOMPSON, surgeon, U. S. Volunteers, First Lieutenant LOUIS T. HESS, assistant surgeon, U. S. Army, and Acting Assistant Surgeon CHARLES F. DEMEX, U. S. Army, for instructions to return to this division; Acting Assistant Surgeon JONAS S. WHITE, U. S. Army, for annulment of contract.

Changes in the Medical Corps of the U. S. Navy, for the two weeks ended November 10 1900.

McCOAMICK, A. M. D., surgeon, commissioned surgeon from November 11, 1899. October 29.
LEDBETTER, R. E., assistant surgeon, ordered to the "Constellation." October 30.
BIDDLE, C., surgeon, detached from the "Texas," when put out of commission, and ordered home to wait orders. October 31.
WHITE, C. H., medical director, detached from the Naval Museum of Hygiene, Washington, on reporting of relief, and ordered home to wait orders. November 1.
BRADLEY, G. P., medical inspector, ordered to duty in charge of the Naval Museum of Hygiene, Washington, November 15.
AMES, H. E., surgeon, detached from the "Kearsarge" and ordered to the "Massachusetts."
BOYD, J. C., medical inspector, detached from the "New York," when out of commission, and ordered to the "Kearsarge."
BOGERT, JR., E. S., passed assistant surgeon, detached from the "New York," when out of commission, and ordered to the "Massachusetts."
ELLIOTT, M. S., passed assistant surgeon, detached from the Naval Station, Port Royal, and to duty on the "Annapolis" when placed in commission.
GARTON, N. M., assistant surgeon, detached from the "Massachusetts" and ordered to the "Indiana."
BUTLER, J. ST. J., assistant surgeon, appointed assistant surgeon from October 26, 1900.
MOORE, J. M., passed assistant surgeon, ordered to Naval Station, Port Royal.
SHIPP, E. M., passed assistant surgeon, detached from Norfolk Hospital and ordered to the "Michigan."
WILSON, H. B., passed assistant surgeon, detached from the "Michigan" and ordered to Naval Hospital, Norfolk, Va.
SPRATLING, L. W., passed assistant surgeon, detached from Yokohama Hospital, and ordered to Naval Station, Cavite, P. I.
DOUGLASS, S., pharmacist, ordered to additional duty on the "Massachusetts."

Changes in the U. S. Marine-Hospital Service, for the two weeks ended November 8, 1900:

NYDEGOER, J. A., passed assistant surgeon, is relieved from duty in the Philippine Islands and directed to return to the United States at once. October 31.
COFEA, L. E., assistant surgeon, is relieved from temporary duty at Philadelphia, Pa., and directed to proceed to Washington, D. C., for examination for promotion. November 1.
COAPT, G. M., assistant surgeon, will proceed to Cairo, Ill., and assume temporary charge during absence of medical officer. November 1.
KING, W. W., assistant surgeon, will proceed to San Juan, P. R., on special temporary duty. October 26.
HOLT, J. M., assistant surgeon, is granted leave of absence for 7 days. November 1.
BOGESS, J. S., assistant surgeon, is relieved from duty at Chicago, Ill., and directed to proceed to Philadelphia, Pa., and report to medical officer in command for duty. November 1.
GOLDSBOROUGH, B. W., acting assistant surgeon, is granted leave of absence for 4 days. October 27.
CARMICHAEL, D. A., surgeon, granted leave of absence for 30 days from October 23.
MAGRUDER, G. M., surgeon, granted leave of absence for 7 days from November 17.
WERTENBAKER, C. P., passed assistant surgeon, to proceed to Natchez and Jackson, Miss., on special temporary duty.
YOUNG, G. B., passed assistant surgeon, granted leave of absence for 2 days. November 3. Granted leave of absence for 5 days on account of sickness. November 8.
FOSTER, M. H., assistant surgeon, to proceed to Seattle and Tacoma, Wash., on special temporary duty. November 3.
GIBSON, R. H., hospital steward, granted leave of absence for 30 days from December 7.

The sale of morphia by pharmacists without a prescription is being considered by the Council of the Medical Association of the Seine at Paris. The development of "specialties" has also made it possible for druggists to sell any forbidden drug under the guise of these preparations. One pharmacist has been imprisoned 8 days and fined 1000 francs for habitually selling morphia to a lady without the sanction of a physician.

foreign News and Notes.

GREAT BRITAIN.

Edinburgh Royal Infirmary.—The new pavilion of this institution was formally opened October 26, by Princess Henry of Battenberg.

Surgeon-Major Babbie, of the Royal Army Medical Corps, has received the Victoria Cross in recognition of his valuable services and conspicuous heroism in South Africa.

Prof. A. W. Hughes, of King's College, who recently returned from South Africa with enteric fever, is seriously ill. Engorgement at the base of the right lung has improved, but was followed by phlebitis.

Compulsory Notification of Phthisis in Dublin.—The Public Health Committee has sent a report to the corporation recommending that for one year as an experiment pulmonary tuberculosis be made a compulsory notifiable disease.

Black Smoke Nuisance.—An effort is being made to abate this nuisance at Manchester. Deficient boiler accommodation and had stoking are stated as causes and manufacturers have been notified to remedy these defects. When this is done the stokers themselves will be held responsible for the excess of smoke.

Women and Medicine in Manchester.—The Owens College is to admit women students to the infirmary and medical department. A woman has been appointed resident medical officer to the Clinical Hospital. The Pathological Society, by an overwhelming majority, has decided to admit medical women to its membership.

Infection from Seborrhea.—A certain hospital reports a series of postoperative suppurations, the cause of which was finally traced to the fact that the house-surgeon was suffering from seborrhea. In such cases it is stated that dipping the hands for 15 seconds in chirol forms a protective covering through which sweat or germs cannot pass.

Winds and Tuberculosis.—Dr. W. Gordon, of Exeter, has demonstrated that the mortality from phthisis is uniformly higher in districts most exposed to the wind. This has an important bearing on the climatic treatment of tuberculous patients. The editor of *The Medical Press* emphasizes the value of such investigations in every district to locate the unhealthy areas.

Liberality of Physicians.—Though physicians give gratuitous services to hospitals it has been said that they rarely subscribe to the funds of these institutions. A notable instance as disproving this statement is found in the case of Dr. A. Garrod Thomas, who donated £5,000 as the nucleus for a fund to erect a new hospital at Newport. A new building costing £30,000 is the outcome of this generosity.

Fees of Medical Witnesses.—It is stated that the new Government will have to deal with a question that is assuming great importance in the medical world, viz., the remuneration of medical witnesses. A physician now receives 1 guinea for attending an inquest, adjourned perhaps and thus lasting several days, and 1 guinea for making a post-mortem. In police courts the pay is a half-guinea per diem. This is a pecuniary loss to a busy practitioner.

Typhoid Fever and Mangles.—Dr. Joseph Priestly reports an epidemic of 41 cases of typhoid fever in Lambeth Vestry, the outbreak being confined to 3 streets. The spread of the disease could not be traced to the ordinary channels of infection, but the cause was finally discovered to be the promiscuous use of mangles. There were 4 in the affected area and 26 cases of fever were among the customers of these mangles. Clothes which had not been properly disinfected were washed with those of the neighbors, and thus spread the infection. Of the 41 cases, 21 were in children under 12 years of age. Dr. Priestly believes that a positive Widal reaction is of great diagnostic value.

The new science laboratories of King's College, London, were opened October 30, the principal address being made by Lord Lister. It was stated that this addition was a happy coincidence, coming, as it does, when King's College is becoming one of the colleges of the reconstituted University of London. Lord Lister would prefer to keep the examining and teaching duties separate, as they were formerly when the old university was the imperial examining institution.

The Presidency of the Royal Society.—Lord Lister's tenure of office having nearly expired, great interest is being manifested in the choice of his successor. Several prominent candidates are mentioned. The society has made great advances during Lord Lister's presidency and it will not be easy to fill his place. The International Catalog of Scientific Literature is an important work undertaken by the Society during his term of office. This project is so far advanced that cataloging will be commenced with the new century.

Vaccination in Gloucester.—At the meeting of the Gloucester Board of Guardians held on October 23, it was decided to forward to the Local Government Board full particulars respecting the continued neglect of the vaccination officers to carry out the order of the Local Government Board. It was stated that in 1898, out of 1 600 births there were between 200 and 300 vaccinations, and in 1899 there were 700 vaccinations, but since then, owing to the loose manner in which the Act was administered, the number had greatly diminished.—[*The Lancet*]

Gifts to Leeds Medical Charities.—The late Mr. Robert Arthington, who recently died at Teignmouth, made an order shortly before his death transferring the sum of £20 000 to the names of the treasurer of the Leeds General Infirmary and of a member of the Committee of the Leeds Hospital for Women and Children. Of this sum £12 000 is to provide a semi convalescent hospital for woman in connection with the Leeds Infirmary, and the remaining £8 000 is to go to the fund for rebuilding the Hospital for Women and Children.—[*British Medical Journal*.]

Fees for Lunacy Certificates.—At the meeting of the Davenport Board of Guardians held on October 26 it was stated that letters had been sent to 25 medical practitioners asking whether they would accept half a guinea as the fee for the examination of pauper lunatics. Replies were received from 18; 6 agreed to accept the fee, 10 were against doing so, and 2 declined to express an opinion. After some discussion the guardians resolved to write to the bench of magistrates asking them to appoint one of the 6 medical practitioners to examine supposed cases of insanity in paupers.

Alleged Dissecting Scandals.—The Lambeth Guardians having raised a question as to the disposal of bodies used for dissecting purposes at St. Thomas's Hospital the instructor of anatomy, in answering their letter of inquiry, said in part: "In answer to your letter to the steward of this hospital, I beg to inform you that a burial service is read over the remains of bodies which have been dissected. They are all treated in the same way as parish cases which have not undergone anatomical examination, that is to say, the friends and relatives, if any, assemble in the church to hear the service, after which they proceed to the grave for the committal of the body."

CONTINENTAL EUROPE.

Cancer in Hamburg.—The rate of mortality from cancer in Hamburg rose from 71.63 per 100,000 persons in 1872 to 97.82 in 1898.

Jenner Exhibit at Paris Exposition.—This was designed by Professor Hubert, of Russia, and is a history of vaccination with special reference to Jenner himself.

An Annual Congress of Russian Surgeons has been organized, the first meeting to be held at Moscow, December 28-30, 1900. Professor Dakanow has been elected the first president, and Professor Bubrow vice-president.

The collection of utensils pertaining to the care of the sick now at the University of Berlin, are to be made into a museum, under the direction of Prof. Martin Mendeleohn.

Smallpox Decreasing.—Since the year 1862 the mortality from smallpox has decreased in Prussia and Bavaria from 51.6 to 0.7; in Austria from 75.2 to 38.6; in Belgium from 79.5 to 18.2; in England from 25.6 to 2.9; and in Sweden from 26.9 to 0.5.

Iodoform and Calomel.—Dr. Toth, of Brunswick, has used this combination, recommended by Prof. Sprengel, with gratifying results, especially in suppurating scrofulous glands. One advantage is that the mixture can be used on persons who have an idiosyncrasy to iodoform alone.

Smallpox in Paris.—Some isolated cases of smallpox have been reported and the Prefect of Police has advised the vaccination of the inhabitants. The disease appeared earlier in the year and was supposed to have been entirely suppressed. There are no fears of an epidemic.

Dr. Cajal's Laboratory.—It is announced that the Spanish Government has made substantial contributions for the enlargement of Dr. Ramon y Cajal's laboratory at Madrid, also for its yearly maintenance, and has, in addition, bestowed a not insignificant pension on the distinguished scientist.

Leprosy in Switzerland.—A case of leprosy has been discovered in Zürich, the patient having come from Brazil in search of treatment at the hands of a specialist "who, discarding drugs as poison, makes a therapeutic specialty of vegetarianism and hydrotherapeutics." The bacillus of lepra was demonstrated.

Notification of Infectious Diseases in Rome.—The following is the municipal law governing physicians in Rome: Physicians, surgeons, and midwives who treat or assist patients with smallpox, malignant pustule, measles, scarlatina, enteric fever, typhus, diphtheria, croup, whooping-cough, puerperal fever, cholera, dysentery, or other disease which is contagious or suspected to be so, as well as cases of hydrophobia or of syphilis transmitted by a hired wet-nurse, are required to give immediate notice of such to the Municipal Bureau of Hygiene.

The Immunities and Proclivities of the Arab Races.—At a recent meeting of the Société de Biologie in Paris, M. Remlinger called attention to the immunity of the Arab to typhoid fever and other diseases of the digestive tract, and his susceptibility in regard to pneumonia, phthisis, and other affections of the respiratory organs. He attributed these peculiarities to the fact that the Arabs were accustomed from infancy to drink contaminated water, and that they had thereby undergone a kind of immunization relative to enteric fever and kindred diseases. On the other hand, from always breathing the pure air of the deserts their lungs were particularly liable to suffer from atmospheric impurities.—[*British Medical Journal*.]

The Cellular Diagnosis of Tuberculous Meningitis.—M. Widal and others have reported the results of researches into the histology of the serous effusions of the various forms of meningitis. Normal cerebrospinal fluid contains no morphologic elements, neither are any present during the course of many of the acute diseases. In acute meningitis various morphologic elements are present. In 12 cases of tuberculous meningitis, the diagnosis being confirmed by autopsy, lymphocytes were numerous in the fluid. In 2 cases of cerebrospinal meningitis the polynuclear cells were to a marked degree more numerous than the lymphocytes. Lymphocytosis is, therefore, considered characteristic of the effusion of tuberculous meningitis.

MISCELLANY.

Leprosy in Asia.—It is stated that India has about half a million, China probably as many, and Japan 200 000 registered cases of leprosy; and these lepers, young and old, are treated as unclean and turned adrift upon the highway and shown neither mercy nor kindness.

Malarial fever is unusually prevalent at Delhi. Many of the cases are thought to have been caused by the collapse of so many of the servants' houses during the recent heavy rains and the consequent lack of shelter.

Bhagvat Sinhjee, ruler of the Indian State of Gondal, is a medical man. He holds degrees from Edinburgh, London and Oxford. A visit to his sons in England was given up in order to help avert the famine disaster in his State.

Cancer in New South Wales has been increasing much faster than the growth of the population. For the years 1860-64 the rates for males and females were 1.84 and 2.17 per 10,000 respectively. During 1895-99 the rates were 5.18 for males and 5.08 for females.

Enteric Fever in India.—The authorities are attempting to lessen the great mortality from this disease among the British troops in India. During the past this has amounted to about half the total mortality. Beginning with January, native cooks will be abolished and Europeans substituted, it having been shown that enteric fever lessens rapidly when soldier cooks are employed. The Army Medical Service in India is accused of thinking itself superior to the dictates of common-sense modern science, but recent developments point to the awakening of its members in this regard.

Birth-rate After Famine.—The vital statistics of the provinces in India which suffered from famine in 1897 show a remarkable increase in the birth-rate during the 2 years following the famine. The districts which suffered most showed the greatest increase. A question is whether the cause is physical or social. Many marriages may have taken place after postponements due to the famine. The cause may be physiological and a proviso of nature to replace the loss by famine. It will be interesting to note whether this increase in birth-rate follows the severe famine which is now abating.

Foreign University Intelligence.—BERLIN: Dr. Moritz Litten has been appointed extraordinary professor of internal medicine. BRESLAU: Dr. Alfred Schafer, formerly of Harvard University, succeeds the late Professor Born as extraordinary professor of anatomy. HEIDELBERG: At the beginning of the summer semester of 1901, Professor Rossel of Marburg, will succeed the late W. Kühne as professor of physiology. GÖTTINGEN: Dr. Meissner retires from the chair of physiology on account of bad health.

Mr. W. W. Astor has made a donation of £10,000 to the University of Cambridge. A new building for pathology and medicine will be erected.

Obituary.—MR. WILLIAM ANDERSON, surgeon at St. Thomas' Hospital and professor of anatomy in the Royal Academy of Arts, October 27. He served as principal of the Naval Medical College, Tokio, from 1873 to 1880, and was one of the chief authorities on arts in Japan.—GEORGE THOMAS GALBRAITH, at Stirling, October 24, aged 83.—JONES LAMPREY, at Southsea, October 29, aged 78.—PROFESSOR VAN HENKOLM, of Leyden, Holland.—DR. TOMASHEVSKI, for 40 years director of the Children's Hospital in St. Petersburg.—DR. MAXIMINO TEIJEIRO, professor of clinical surgery in the University of Santiago, Spain.—DR. SEATON, inspecting officer of the Royapuram Emigration Department, November 1, of cholera.

The Plague.—There are at present only 8 inmates of the plague hospital in Glasgow and these are all convalescent. No suspected cases occurred during the month of October. The case on board the *Ben Lomond* at London from the Philippines has given rise to no new cases. The mortality in India has slightly decreased, probably due to the lessening in severity of the famine. The mortality in Bombay this year is but half that of the average for the preceding 4 years. Maudvie is the district always furnishing the greatest number of cases, and entire evacuation has been suggested as the remedy. In Mysore city the alarming increase previously reported continues. A great outbreak is reported from the Kolar gold fields. A slight increase in cases but a decrease in deaths is reported from Mauritius. The plague seems to be subsiding in Hong Kong. It has usually subsided in the autumn and there is reason to believe that this year will prove no exception.

South African Medical News.—Dr. J. Lynn Thomas writes very entertainingly of his hospital experience. Lodged bullets should be left for 2 or 3 weeks before extraction, even if only under the skin. A peculiar result of Lee-Netford and Mauser bullet-wounds is a small skin scar and a relatively large, subcutaneous scar in the soft tissues. This result is believed to be due to the impairment of tissue vitality by hydrodynamical displacement of the tissue-fluids caused by the great velocity of the bullets. Thomas doubts the efficacy of steel breastplates to protect the heart during battle, for the reason that the soldier is as likely to receive a heart-wound from the rear or side as in front, owing to the great penetrating power of modern firearms. One soldier narrowly escaped penetration of the heart by a bullet which entered through the right ileum.

The practitioner's duty in the treatment of acute intestinal obstruction is summarized by Maylard (*The Practitioner*, November, 1900). He says there are no cases which occur in general practice that present greater difficulties in diagnosis than the subject here treated. Various symptoms and signs are enumerated which he says might easily apply to one of many intraabdominal disorders. He says, however, that the general practitioner can in almost all cases determine when there is "peritonism," whatever may be its cause. This being determined there remains but one thing to do—open the abdomen. It is necessary that operation be done early to prevent disastrous consequences not only from the lesion but from the absorption of toxins. When acute obstruction occurs the general practitioner should inject cocaine and open the abdominal cavity, bring the intestine into the opening and form an artificial anus which will relieve the condition temporarily. If need be a general surgeon can deal with the trouble later. The author suggests, however, that gastric or intestinal perforation presents a very different problem. But even here the general practitioner should operate if the surgeon cannot be had on short notice, for delay means certain death. Maylard has devised a portable operating table which is especially suitable for the practitioner not connected with a hospital. If the condition has passed beyond the initial stage and vomiting has supervened, the stomach and large bowel should be thoroughly washed out and a nutrient enema given before operation. Maylard believes in opening the gut and drawing it up the pent-up contents before seeking for the obstruction. In case of perforation, whether the abdominal cavity shall be flushed out or merely wiped out depends on the general or local condition. If in doubt flush out thoroughly. Before closing the bowel an injection of $MgSO_4$ in solution directly into the bowel-lumen acts well. [A.B.C.]

Suprapubic vs. Vaginal Section.—A. E. Benjamin (*St. Paul Medical Journal*, October, 1900) advocates the suprapubic incision because it minimizes the danger of incomplete operation, since the operator is more likely to detect unsuspected lesions. Since the wearing of gloves has become almost imperative in surgery the vaginal sectionist is deprived of part of the sense of touch by wearing them, making the method less accurate. In general all abscesses low in the pelvis are best drained through the vagina. When this is done early the appendages are frequently saved, the adhesions above melting away as the pus disappears. When pyogenic multilocular cystic tumors are opened from below, they should be examined bimanually in order to open into all the compartments. Small cysts, simple or dermoid, small subserous fibroids of the uterus, not large, may be removed by the infrapubic route if the patient should have thick abdominal walls and a large vagina. These same growths, however, under ordinary circumstances are more easily removed from above. Extrauterine pregnancy diagnosed before suppuration occurs, or at the time of rupture, should always be operated on from above, as it is the safer plan. Adherent and diseased tubes, when attacked through the vagina, are not readily pulled down nor the stump firmly ligated. Concealed secondary hemorrhage may occur. When adhesions are broken up through the vagina they often recur and have to be operated again and from above to be cured. The original operator often loses sight of these cases and the curative work is done by another surgeon who recognizes the limitation of vaginal operations. [O.C.C.H.]

1.—Cantlie believes that the **most potent agent in the spread of plague** is undoubtedly contact with persons suffering from the disease. The skin is at the present time considered by the majority of observers to be the channel by which the plague bacillus finds entrance to the system. The exact method by which human beings become exposed to plague is not, however, definitely known. The average period of incubation is from 3 to 5 days. The onset of plague is generally sudden. A few cases in every extensive epidemic exhibit a rash almost identical with that in malignant typhus. The temperature in a typical case of **bubonic plague** of moderate virulence follows a fairly constant course. During the first 2 days the temperature rises gradually until perhaps it attains a maximum of 104° or 105°. During the third and fourth days it usually remains high, but toward the end of the fourth day it falls, and may approach or even fall below the normal. Toward the end of the fifth day or on the sixth day of the illness an increase in temperature is again to be expected, but the fever gradually subsides after the bubo has burst and discharged. When, after the second rise and fall in temperature, fever recurs, it generally signifies a septic infection, and is usually followed by a fatal result. **Pneumonic plague** is usually ushered in by a rigor, dyspnea, cough, a high temperature, and marked prostration. Blood does not usually appear in the sputum until after 24 hours' duration of the illness. The signs and symptoms are peculiarly evanescent; and a patch of pneumonic tissue, dull today, clears up tomorrow, and another part of the lung becomes affected. The pneumonic variety of plague is a most rapidly fatal form of the disease, the patient usually dying on the third or fourth day. In **septicemic plague** the severity of the onset is such that the patient seems struck down as if by an active poison, and the prostration from the first is so extreme that the strength of the patient seems unable to resist the depressing influences at work. There may be no bubo. As a rule every gland in the body, whether in the limbs, abdomen, or thorax, is found, postmortem, to be somewhat enlarged; and the name "polyadenitis" well describes the condition. The lungs, after death due to pneumonic plague, appear edematous, engorged with venous blood, and are the seat of basal congestion and of patchy consolidation. The pleural surfaces are usually dotted with petechiae, and occasionally with fair-sized subpleural hemorrhages. The linings throughout the respiratory tract are reddened, injected, and show here and there hemorrhages in the submucous tissue; a frothy blood-tinged mucus is commonly found occupying the passages. In septicemic plague the glands over the whole body are congested and swollen, in most cases to only a small extent, but in one group, and frequently in one gland of the group, adenitis has advanced considerably. [J.M.S.]

2.—Walford describes the sanitary measures adopted at Cardiff after the occurrence of a case of plague in one of the crew of the steamship *South Garth*. [J.M.S.]

3.—Savage and Fitzgerald describe the clinical and pathological features of the above case. The patient was a donkeyman aged 38 years. His illness began on September 21, with pain all over the body, lassitude, weakness, and severe headache. Six days afterward he took to his bed with pains in the groins and back, faintness, constipation, and fever. On the fifth day afterwards he was seen by one of the authors at his home. He was then obviously very ill, with high temperature, rapid pulse and respirations. There was an enlarged gland about the size of a small walnut in the right inguinal region. At 6.15 on the same evening he was admitted to hospital in a state of collapse. His trunk and extremities were covered with a dusky-red macular rash, which disappeared on pressure. The spleen was considerably enlarged, and the liver could be felt below the ribs. There was diarrhea of a yellow, offensive character; the urine was copious and passed involuntarily; specific gravity 1.018, acid; no albumin. The patient died October 4. On October 2 cultures were made from the bubo, from the blood that exuded from the wound made by tapping the bubo, and from the blood from the finger. The next morning it was possible to make a provisional diagnosis of plague. This was founded upon examination of the films from the blood and from the cultures. Both coverslip preparations made from the blood showed bacilli in considerable numbers, quite indistinguishable from *B. pestis*. Of the cultures, the only one that showed any growth was an agar slope made from the bubo fluid. To complete the bacteriologic diagnosis the growth on the agar slope, after 24 hours, was scraped off with a sterile platinum loop, made into an emulsion with sterile broth, and 2 cc. was injected subcutaneously into the neighborhood of the left knee-joint of a young guineapig. Widal's test was made; but no signs of reaction were obtained in 2 hours with dilutions 1 in 30 and 1%. The inoculated guineapig showed no symptoms until 2 days later, when it became very quiet. It died nearly 3 days after the inoculation. Great swelling and hemorrhagic exudation were found in the left groin. The individual glands could not be separated. Films from this exudation, stained by carbol fuchsin, showed numerous bacilli. *B. pestis* in pure culture was obtained from the spleen, the left lymphatic glands, the liver, the kidneys, and the heart-blood. At the postmortem the glands in the right groin were visibly enlarged; these were removed *en masse*, and subsequently it was a matter of great difficulty to separate the individual glands owing to the great infiltration around them. In some places this infiltration was hemorrhagic. The larger glands when cut across were of a pinkish-red color. The spleen was a dull purple color, and very considerably enlarged; its under surface was hyperemic and bloodstained; its veins were engorged and its substance softened. The entire surface of the liver was studded with a number of whitish, irregularly-shaped bodies, varying in size from that of a pea to that of a bean, which on section showed a soft, friable, caseous, pinkish-white material. These areas were sharply marked off from the surrounding liver-substance and no signs of inflammation, visible to the naked eye, were seen around them. No macroscopic hemorrhages were seen. Sections of one of the enlarged right inguinal glands stained by eosin and hematoxylin showed great vascular engorgement with numerous blood extravasations, both in the gland and especially in the periglandular tissues. Throughout the gland, but especially in patches, there was well-marked infiltration of the tissue proper with small cells, apparently leukocytes, with deeply-staining nuclei. The well-defined whitish areas found throughout the liver were further examined in sections. They showed a varying amount of degenerated liver-substance, present for the most part as isolated strands of a few cells, while between the cells were very numerous small cells, apparently leukocytes and pus cells. In these areas were a number of small, more deeply staining masses, which, examined with a very high magnification, could be seen to consist almost entirely of *B. pestis*. In the enlarged glands of the right groin coverslip preparations showed a few bacilli, but they were by no means numerous. Cultures from the spleen and kidneys showed a mixed growth of *B. pestis* and other bacilli; from the liver a pure culture of *B. pestis*, and from the heart-blood and lungs a well-marked growth of foreign organism, but no plague

bacilli. Coverslip preparations from the liver, kidneys, and spleen showed scarcely any plague bacilli. [J.M.S.]

4.—Rees discusses the **bacteriology of plague**. Inasmuch as the microorganism does not produce spores and possesses such low powers of resistance outside the body, it is improbable that infection takes place to any great extent through the air; it must under ordinary circumstances take place by close contact. The microorganism may gain entrance to the body by any or all of the following ways: (1) By the skin or mucous membrane; (2) by the respiratory tract, and (3) by the gastrointestinal canal. In order to obtain material for bacteriologic examination in bubonic cases a sterilized needle of an antitoxin syringe should be plunged into the gland, when a sufficient quantity of fluid can be readily obtained. In mild cases it is preferable to make a small incision and remove a small piece of the gland. In pneumonic cases the sputum should be collected in the ordinary way. In septicemic cases it is best to remove a sufficient quantity of blood directly from a vein by means of an aseptic hypodermic syringe. It is good practice to examine the blood in all cases of plague. The infective material obtained from one of the above-mentioned sources should be dealt with in the following way: Two coverglass preparations should be made, and one stained with an ordinary aniline dye, such as weak carbol-fuchsin, and the other by Gram's method. The presence of short bacilli, exhibiting bipolar staining and tending to arrange themselves in pairs, or short chains, and which are decolorized by Gram's method, is highly suggestive. Negative evidence, however, is of less value, and should never be relied upon in suspicious cases. In blood examinations it is best to make the preparations on slides. The bacilli are usually present in very small numbers in the peripheral blood, and a larger amount of blood can be reviewed more rapidly than if a coverglass preparation is employed. Ordinary broth and agar-agar cultures should be made, and their characters studied both macroscopically and microscopically. Haffkine's stalactite growth should also be tried. Guinea pigs should be infected. The diluted blood-serum obtained from a case of plague is said to cause clumping with plague bacilli, although hitherto this has not proved of practical value. The reaction can usually only be obtained late in the disease, and even then it is not always present. Rees is of the opinion that the plague bacillus is best regarded as belonging to the septicemic group of pathogenic microorganisms. The plague bacillus does not produce pus, but it can cause necrosis of tissue. Buboes that contain the bacillus as a pure infection may resolve or slough. If they suppurate it is generally due to staphylococcal and streptococcal infection. [J.M.S.]

5.—Delepine believes that the **varieties of plague** depend (1) on the channel of entrance; (2) on the virulence of the microorganisms; and (3) on the quantity of the bacilli. The bubonic type is produced in the guinea pig by infecting slight cutaneous wounds with a virulent culture of the bacillus (or by injecting subcutaneously various quantities of an attenuated culture). Septicemic plague was produced according to Roux's method by applying the bacilli with a small soft camel's-hair brush to the nostrils of guinea pigs. In one case the author used an agar culture which had been kept for nearly 5 months in a cupboard at the temperature of the laboratory. For another case he selected an agar culture that had been isolated 9 days previously from a fatal case. In both cases there was evidence of general discomfort before the end of the third day, and both animals died between the fifth and sixth day after the painting of the nostrils. The most interesting feature of plague pneumonia is that it can be produced with bacilli, the virulence of which is so attenuated that they do not produce the disease by subcutaneous inoculation. The gastrointestinal form was induced in some mice, of which the author placed 2 in a cage that had been occupied by 2 guinea pigs that had died of plague, and 2 others that he kept in a clean cage, and that he fed on materials that had been mixed with some of the excreta of a guinea pig also dead of plague. The first 2 mice died in about 96 hours; the last 2 died in about 72 hours. They all seemed to have succumbed to some mixed form of infection. The bacillus was recovered in one case only. A gastrointestinal form of plague is not usually recognized as a clinical form of human plague. Delepine has not yet been able to produce localized cutaneous lesions, not followed by

lymphatic extension. The 3 chief types of human plague correspond to the 3 types of infection, the first 2 being determined by the channel of infection, the last being capable of arising whenever the resistance of the tissues is considerably reduced, or the virulence or quantity of the bacilli very great. It will be noticed that in all cases the lymphatic glands are liable to be affected, but that typical axillary and inguinal buboes are produced chiefly in connection with cutaneous infection of the extremities, whilst cervical buboes may be produced as a result of infection of the skin of the head and neck, or of the nasal or buccal mucous membranes. In the case of infection through the air-passages the most characteristic bacteriologic feature is the presence of plague-bacilli in the bronchial and nasal discharges. Finally, in the rapidly fatal forms, without marked localization of lesions, the blood contains a large number of bacilli. In the experiments recorded above, the blood was invariably found to contain bacilli easily demonstrable by direct microscopic examination and cultivation, whatever mode of infection had been adopted. In the cases of mixed infection which were produced artificially, the plague bacillus could be easily separated from the associated cocci. Two methods of infection may be used for diagnostic purposes: 1. Subcutaneous inoculation, for which mice and guinea pigs are especially suitable. 2. Infection through the air-passages, obtained by painting the nostrils with the products under investigation. This method is especially suitable when products of low virulence are being studied. For this method of experimental infection the guinea pig is especially suitable. In practice, the first steps to be taken would be to make a microscopic examination (1) of material obtained from a bubo or from the edematous tissue surrounding it; (2) of blood obtained from the tip of a finger or from the lobe of an ear; (3) of expectoration in suspicious cases of pneumonia. In ordinary cases such an examination presents no difficulty and can be carried out very rapidly. Almost any of the anilin dyes in common use can be used for the purpose of staining coverglass preparations. The slightest carelessness in such work is dangerous. Animals under observation should be kept in a separate room, in glass jars covered with fine gauze, weighted lids. For additional security the jars should be placed in a larger case, constructed very much like a meat safe, but entirely made of metal and glass. This outer case should entirely prevent rats, mice, or even insects, from having access to the animals or their food. The skin of animals which have to be dissected should be well soaked with an acid solution of perchlorid of mercury (1 in 500) before the animal is opened, and the dissection should be made over a tray containing some of the same solution. The body and organs which are not preserved in suitable preservative fluids should be at once destroyed by fire. Laboratory attendants should not be allowed to touch any infected animal or products before these have been thoroughly disinfected. [J.M.S.]

6.—Stewart contributes a paper on **The methods of making antitoxic and preventive fluids**. The intracellular poisons of the dead microorganisms are mostly concerned in conferring protection, but Haffkine injects the broth in which they have grown as well. The object is to counteract an attack of plague in an inoculated person—supposing he became infected—by previously accustoming the tissues to the poison given out by the microorganism in the cultivation medium. This theory assumes that the intracellular poisons induce a bactericidal power in the tissues, and that the extracellular poisons induce antitoxic properties that would come into play supposing the bactericidal power were insufficient to prevent infection; that is to say, if the person did contract plague. Since a dead culture only is used the prophylactic is in no sense a serum. The false use of the word serum for what is really a vaccine is to be deprecated, for it gives a wrong notion of what the fluid really is. The vaccine is a sterilized culture of the plague microorganism in broth. The microorganism should be obtained fresh from a case of plague, or from a culture in which the virulence has been kept up. In India, where the religious prejudices of Hindu and Mohammedan have to be allowed for, the broth is made with goat's flesh. The antitoxic serum of Yersin is used as a curative agent for plague. It also acts as a prophylactic agent, but the immunity conferred only lasts about 15 days. The principle of this serum is the same as that of antidiptherial serum and others of like

nature. Living cultures of the plague bacillus were administered to a horse by intravenous injection. The best results from the use of antitoxic serum thus made were obtained at Canton and Amoy in the summer of 1896. Later, cultures killed by heat, and toxins formed in the cultivation media were used. The results with this serum gave the least good results. On account of the inferior results of this serum and considering the progressive encroachment of plague the Pasteur Institute decided to prepare several horses vaccinated first with cultures killed by heat and afterward with living cultures, as was done in the first instance. This serum was used at Oporto in 1899, and gave somewhat better results. Lustig's method of preparing vaccine is based on the observation that a nucleoproteid which he succeeded in separating from the bodies of plague microorganisms is a substance that induces immunizing properties when injected; neither the metabolic products of growth nor toxins are used. Lustig proposes to use this solution as a prophylactic. He also immunizes horses with it by repeated inoculations during a period of 3 or 4 months. The serum has been prepared in Bombay and tried at the Arthur Road Hospital. So far, there has been no report of the use of the nucleoproteid used as a prophylactic, if it has been tried. The results of the curative serum were not at first very satisfactory, but lately better results seem to have been obtained. Dr. Polverini, in a report to the Bombay Municipal Committee, states that in 475 cases treated a recovery percentage of 39 was obtained. [J.M.S.]

7.—Christie used **Haffkine's prophylactic** in Calcutta in 1898. For an adult male the ordinary dose of the fluid then provided was 5 cc. She used to give a woman 4 cc., girls, aged from 10 to 14 years, 3 cc., and children from 2 to 10 years old, from 1½ to 3 cc., according to age. The reaction in many cases began at once with a pricking sensation at the site of inoculation and the gradual formation of a hard, tender, red swelling a few inches in circumference. The temperature rose, in the cases in which it was taken, within 6 hours of the inoculation, and it was highest on the night of inoculation. In a few cases it only reached 99.6° or 100° F. In the majority of instances it rose to 102° or 103°. The fever rarely lasted more than 2 days, though the arm remained more or less painful and tender for a week or 10 days, and a small, hard nodule often remained for a few weeks. The day after the injection a red, hot, hard swelling of the skin and subcutaneous tissue of the arm was noticed, that rarely spread above the shoulder, however, but which often extended to the elbow or even to the wrist. The margin of this swelling was as well-defined in many cases as in erysipelas. The axillary and cervical glands were sometimes swollen and tender. Many patients complained of shooting "rheumatic" pains in the shoulder and elbow-joint. Some subjects vomited or had diarrhea, others suffered from nausea, syncope or shivering. [J.M.S.]

8.—In the **organization and conduct of plague laboratories** it must be remembered that comparatively little is known as to the methods of infection; more than that the disease is extremely infectious. The mere handling of a rat dead of the plague has been sufficient to cause death, and flies and fleas are quite capable of conveying sufficient virus to cause the disease. As this is so, no precautions can be too elaborate, and the minutest details in the construction and furnishing of the laboratories, and in the technic of the postmortem examinations upon man and animals, must be attended to. According to Pakes, a laboratory for the investigation of plague should consist of 3 rooms: (1) An anteroom for the preparation of media, cleaning of used vessels (after sterilization), and for the many other duties which devolve upon a laboratory assistant; (2) the laboratory proper; and (3) a room wherein to keep all infected animals. If the laboratory forms part of a larger building, it should be isolated, as regards communication, from the rest of the building, and so arranged that the only ingress to the laboratory is through the anteroom, and to the animal room through the laboratory. The walls and ceilings should be made of nonporous material, and should have a glazed surface without break; the floor should be of cement or of grooved tiles well set in cement. The windows must be large, and so arranged that the lighting is uniform; the window-sashes of iron, and not projecting into the room. All corners must, of course, be rounded off. The ventilation of each room should be separate, and the outgoing air made

to pass a gas flame. The source of heat should be, whenever possible, a gas stove, and the source of artificial light gas or electricity. Every endeavor must be made to prevent the formation and collection of dust, and to this end it is advisable to have the floor moistened with a solution of corrosive sublimate containing a little glycerin. The amount of furniture necessary is not great. In the conduct of the laboratory the bacteriologist himself should alone handle the infected material, cultures and animals, even to the extent of feeding the animals. Both the principal and assistant should wear macintosh overalls that must be frequently washed with strong disinfectant solution. When an animal is to be inoculated it should be prepared in the anteroom, only the actual inoculation being performed in the laboratory. During the inoculation both the principal and the assistant should wear rubber gloves, which can be easily disinfected. Unless the hands are covered they would have to be thoroughly disinfected after every inoculation; and in dealing with plague-bacilli, this should be done as seldom as possible in order to prevent the peeling and cracking of the skin, which is the usual sequel to the constant use of disinfectants. Upon the death of the animal it is removed with forceps and fastened on a suitable block of wood, carrying small wooden plugs at the side, by means of string or wire. The cage should at once be placed in the autoclave and sterilized. In making the necropsy gloves should be worn. Upon the conclusion of the necropsy the principal should sterilize all the instruments, calcine the animal, and thoroughly disinfect the bench with the disinfectant solution. All discarded cultures must be at once incinerated, or sterilized in the autoclave before leaving the laboratory. Lastly, the laboratory should be used only for the investigation of plague, no other work of any description should be undertaken. [J.M.S.]

9.—Hosack gives histories of 2 houses in Calcutta in which **plague and influenza occurred simultaneously**. In Calcutta the registration of plague depends in great part on investigation of all deaths made subsequent to death by responsible European medical officers. If along with plague we have influenza contemporaneously epidemic, with a knowledge that both may coexist in the same house, the task of these officers in deciding from the history whether a given death is due to plague or influenza becomes an almost impossible one; for even with every opportunity for full medical examination and observation of the patient, no diagnosis can be more difficult than that of virulent influenza from nonbubonic plague. The leading characteristics of both are identical—suddenness, intensity, cardiac weakness, and a great tendency to nervous developments, meningitis and various paralyses. In both, pneumonia is one of the manifestations of the disease rather than a complication, and in both it tends to be accompanied by indefinite physical signs. Cerebrospinal meningitis is also extremely difficult to diagnose from plague. Altogether, with the 3 diseases all at present sporadic in Calcutta, the task of the district medical officer is not an easy one, particularly as owing to the prevalence of false information he cannot place much reliance on the alleged absence of buboes. Fortunately, cerebrospinal meningitis is practically confined to one locality, and the proportion of influenza to plague, so far as known, is insignificant. But, if the two former diseases increase, the problem of how to register plague will be a difficult one to solve. Cultural and microscopic appearances of microorganisms obtained from some of the patients were those of the bacillus of influenza described by Pfeiffer. [J.M.S.]

11.—Calmette presented to the International Congress of Hygiene and Demography held in Paris last month, a report on the **Part that prophylactic inoculations might play in preventing the spread of plague**. The antiplague serum conferred very strong immunity, which commenced almost immediately after the injection. Unfortunately this immunity lasted for a very short period, rarely exceeding 10 to 14 days. Consequently, when the antiplague serum was used during epidemics as a preventive measure, it was necessary to inject a dose of 10 cc. of the serum every fortnight to give an efficient protection to exposed subjects. The advantages of the method are: (1) The immunity conferred is immediate and almost absolute; (2) the injection of serum being painless, it was readily accepted by every one, even by children; (3) it was never harmful; (4) when the serum was prepared aseptically, the

activity of the preparation remained the same for a long period; in fact, almost indefinitely. The drawbacks are: (1) The resulting immunity was of too short duration; (2) the high price of the serum, and the difficulty of obtaining it in large enough quantities to permit of the population of a whole town being vaccinated every fortnight; (3) the difficulty in making compulsory or general a vaccination which had to be repeated so often. Its use, however, is indicated in the following circumstances: (1) On infected vessels, during the voyage, to prevent the disease spreading among the passengers and crew; (2) in lazarettos temporarily to protect the employes who had to discharge and disinfect the cargo brought by a suspected vessel, or on board of which cases of plague had occurred during the voyage; (3) in docks, custom houses or warehouses (exceptionally) when suspected goods were manipulated; (4) in times of epidemic, for the immediate vaccination of any persons who had been in momentary contact with the patients, or were possibly already infected. The method of vaccination with cultures of *Bacillus pestis* killed by heating to 70° C., which have been applied during the last 3 years on a huge scale in India by Haffkine, possess the incontestable advantage of conferring a longer immunity than that produced by the antiplague serum. The exact duration, however, of this immunity is very variable. It depends on the quantity of microorganisms in the culture, on the age of the culture or its toxicity, and on the method of its preparation. Calmette has undertaken a research, vaccinating by Haffkine's method several series of monkeys, guineapigs, and rats, in order to determine not only the duration of the immunity after 1, 2, or 3 injections of heated vaccinal cultures, repeated at weekly intervals, but more especially to determine at what time after the vaccination immunity began. The author arrived at the conclusion that after a single injection of 3 cc. of a bouillon culture one month old, heated during one hour at 70° C., immunity was established on the seventh day. This immunity lasted on an average 3 weeks in the guineapig and one month in the monkey. Haffkine's vaccination was most useful in infected countries, and for the following reasons: 1. It was possible to prepare in a few weeks, without any difficulty, and at very small cost, large quantities of cultures of the plague-bacillus and, consequently, of the vaccine, since it was only necessary to heat those cultures, one month old, for an hour at 70° C. 2. Persons endured the inoculation of these heated cultures fairly well; it only caused a little swelling and lymphangitis around the seat of inoculation, which lasted 5 or 6 days. 3. It was possible with the heated cultures to vaccinate the population of an entire city or district, and thus suppress the receptivity, and, consequently, all chances of the spread of the disease. The method is, however, open to serious objections, of a nature to prevent public authorities making its application obligatory in infected countries. 1. With M. Sahmbeni, Calmette has shown, during the recent epidemic in Oporto, that animals during the period of immunization with heated cultures are extremely sensitive to very small doses of the virus, doses which were rarely mortal to non-vaccinated animals. It followed that a person in the period of incubation for a slight attack of plague would find the disease considerably aggravated if he submitted during this period to a preventive inoculation of Haffkine's vaccine. The case would almost certainly end fatally. 2. The injection of heated cultures causes a more or less sharp rise of temperature, usually of short duration, but in some cases sufficiently high to make the patients stop work. 3. The heated cultures can be kept for a much shorter period—it did not exceed 6 months—than the serum. The combined action of air and light quickly attenuates the toxicity of these cultures. The cultures therefore must be frequently renewed; old vaccine must not be used. In spite of these objections it must be recognized that the method of vaccination with heated cultures is capable of rendering immense service in times of epidemic, since it is possible to limit almost immediately extension from a focus. Calmette thinks, however, that the use of antiplague serum, which does not present the dangers of Haffkine's vaccination, is more to be recommended for vessels, lazarettos, hospitals, and observation centers, not only because it is an excellent preventive measure, but because, while it is a vaccine, it is at the same time the only efficient remedy that can be employed in the treatment of declared plague. [J.M.S.]

12.—Yersin recently returned from the Far East, and the special correspondent of the *British Medical Journal* was able to find out from him his views as to the **preventive measures** to be adopted in a threatened epidemic and the best means of preventing the spread of the disease. In a village or restricted community the only effective means of preventing the spread of the disease is to evacuate the infected village. Yersin cited the case of one village in which there were 7 cases of plague when the village was evacuated. On the first day after this measure 2 new cases developed, on the second day no case, on the third day 1 case, on the fourth day no case, on the fifth day 1 case, after which no fresh cases occurred in the population. The disinfection of a house, even when carried out under scientific supervision, affords no guarantee that fresh cases will not occur on the house being again inhabited. Even burning an infected house does not prevent the spread of the disease. The inhabitants must not be permitted to return to an infected district for at least 6 months. The ideal plan would be for the inhabitants to have 2 villages—one for the cold weather, which should be vacated for the mountains as soon as spring returns or the disease shows signs of recrudescence. In a large city or town in Europe, such drastic measures are impracticable. In these conditions, in addition to isolation of the sick, the only means of limiting the disease is the inoculation with antiplague serum of all persons who have been exposed to infection; such of these as may be in the incubation period will have a mild attack, or they may die. Disinfection must be carried out as demanded by the sanitary authorities, but its protective powers are not absolute. The serum confers immunity for 15 days only, but if there is further fear of infection, or fresh exposure, the injection of serum should be repeated. With Haffkine's method of vaccination with dead bacilli, or bacilli that has been heated for 1 hour at 70° C., it is impossible to say for how long a period immunity is obtained in man. By this method Yersin has never been able to obtain immunity in animals. He has seen this method of vaccination give rise to great suffering and constitutional disturbance. Possibly a mixture of antiplague serum with a small portion of an attenuated culture of plague bacilli and inoculating man with this mixture may produce a better and more desirable result. Yersin is of opinion that no conclusions can be drawn from the exceedingly mild type of the disease in the recent epidemic of plague in Oporto and in the outbreak in Glasgow as to the severity of possible future outbreaks in the British Isles or elsewhere in Europe. With the plague we must be prepared for any type of the disease. It is quite possible, when in the course of the next few years the bacilli have become acclimatized in their new surroundings, that their virulence will increase, and that we shall see the same severe form of plague as visited Europe in the Middle Ages. [J.M.S.]

13.—At a recent meeting of the Académie de Médecine of Paris M. Vallin made a report on the **epidemics of plague** at Kobé and Osaka, being a summary of the official report by Professor Kitasato, of Tokio, assisted by Drs. Takaki, Shiga, and Moriya. In the town of Kobé (230,000 inhabitants) there were, from November 3 to December 21, 1899, 23 cases of plague, 19 being fatal; while in Osaka, the second city of Japan (750,000 inhabitants), there were, from November 18, 1899, to January 11, 1900, 39 cases, with 37 deaths. Rats, it would seem, played an important part in the development of these two local epidemics. The municipality of each of these two towns paid 10 centimes for every rat dead or alive, and from the middle of November till the end of January 20,000 rats were taken at Kobé and 15,000 at Osaka. Many people also, in order to avoid the disinfection of their houses, either burnt or threw into the canal or river all the dead rats they found. The investigators, on careful examination of the dead rats, found that at Kobé 1 rat in 5, and at Osaka 1 rat in 10, were infected by plague bacilli. [J.M.S.]

1.—Allbutt contributes an abstract of his address before the Royal College of Physicians of London, upon the subject of **Harvey's discovery**. It is chiefly an analysis of the various philosophic movements from the time of the ancient Greeks until Harvey's day, the different systems as they became crystallized, acting as forces antagonistic to new ideas or theories. To all these Harvey appeared as an iconoclast, and, as a matter of fact, his work did perhaps more to overthrow the old speculations and barren metaphysics than that of any other man. To use Allbutt's own words: "Harvey's discovery, under such conventions, burst like an earthquake—under corrupt Galenism, venerable sophistries, current abstractions bequeathed by realism, and long-winded dialectics on critical days, coctions, derivatives, or revulsives, and dogmas based on uncritical subservience to texts." That philosophic speculation is not dead in medicine the following quotation from another portion of the paper may suffice to show: "The content of notions is indeed in inverse proportion to their universality. We may discuss the causes of typhoid fever and bewilder ourselves by forgetting that there is no such thing as typhoid fever, and that the only causes of a general notion are the psychologic causes of its generation in the mind of the thinker at the time; that which is due to objective causes is of course not the general notion but the particular case, a very different matter." [J.M.S.]

2.—Littlewood reviews the entire subject of **appendicitis** and cites cases from his experience without adding much that will be new or of special interest to American readers. He urges that if no improvement is seen in 48 hours from the onset of an attack that the patient should be seen by a surgeon, who will then decide as to the advisability of operation, and states that he has never regretted early operation. [M.B.T.]

3.—Bellamy gives a detailed account of the experiments that have been performed by Schiff and Herzen, in order to prove the important **role played by the spleen in the production of pancreatic ferments**. The experiments of Schiff, which are given in detail, are now old, having first appeared in 1868. They were undertaken as a result of the observations made by a number of physiologists, that, at a certain period after digestion, about 5 hours, the spleen became congested, and increased considerably in weight. Various experiments were performed, all of which seemed to prove that dogs, whose spleens had been extirpated, or whose splenic vessels had been ligated, were unable to produce an active pancreatic fluid. Later, the discovery of zymogen by Heidenheim, and the fact that it could be converted into trypsin by the action of oxygen, seemed to disconcert the apparently obvious results of Schiff's work, but Herzen suggested that possibly the spleen secreted a substance which was poured into the general circulation, and coming in contact with the zymogen, converted it into trypsin. He, therefore, believed that it should be possible to obtain this tryptogenic substance from the spleen itself at the period of its greatest congestion. He found that by mixing a pancreatic infusion and infusion of congested spleen together an actively digesting solution was produced that would dissolve fibrin and albumin; whereas the pancreatic infusion mixed with extract of anemic spleen was without effect. It having been suggested by Heidenheim that this was probably merely due to the excess of oxygenated blood in the splenic extract, a series of experiments were undertaken with extract of anemic

spleen mixed with arterial blood; they were, however, inefficient. It, therefore, seems conclusively proved that the spleen, during its period of turgescence, does secrete some substance which acts upon zymogen and converts it into trypsin, and that this substance has a specific and peculiar action. It is possible that the zymogen excreted by the pancreas before the splenic ferment is elaborated, is gradually converted into trypsin by oxidation in the intestinal tract. In splenectomized animals, proteid digestion appears to be accomplished chiefly in the stomach. [J.S.]

4.—Sheild reports a case of huge **cystic sarcoma of the femur**, in which the diagnosis was obscure. An incision had been made by another surgeon causing infection and converting it into a huge abscess cavity. The patient was seen by several eminent surgeons, and necrosis with abscess, and actinomycosis were suspected. The abscess was opened and part of the growth was removed, revealing its true character. The patient refused amputation at the hip and died from exhaustion a short time later. Another case is reported of ulceration of a toe followed by melanosis of the glands in the groin, and a third case of sarcoma of the tibia simulating abscess. [M.B.T.]

5.—Duprey believes that the **anemia occurring in ankylostomiasis** is often due to the habit frequently associated with the disease, of **eating dirt**. This alone will often give rise to the characteristic symptoms of the disease, particularly the edema of the face and feet, the profound anemia, emaciation, and exhaustion. He mentions several cases in which the worms are not found, although the symptoms of the disease were present. The habit of eating dirt is apparently as irresistible as that of morphia or other drug habits, and the patients will not only deny it, but use all sorts of means to obtain the substance. [J.S.]

6.—Colvin, having had the opportunity of studying several cases of **plague** during the recent epidemic in Glasgow, calls attention to the **difficulty of diagnosis** in the early stages of the disease, particularly when the presence of an epidemic is not suspected. The respiratory symptoms rarely exceeded slight congestion at the base of the lung; the nervous symptoms were often severe, the patient would be very restless, delirious, or dull and apathetic. Diarrhea was frequently present. In one case there was tenderness in the right iliac region, the tongue is not characteristic; the general condition was one of extreme prostration. Of course the characteristic symptom is the appearance of buboes; these, however, are not present in the pneumonic and septicemic forms. In nearly all epidemics the earliest cases are bubonic in type, and the glands most frequently affected are those in the groin. The Widal action is always negative. [J.S.]

7.—The patient, a man of 29, had had 2 attacks of influenza and scarlet fever in youth. After the second attack of influenza he suffered from persistent shortness of breath. The area of cardiac dullness was increased and the action of the heart was irregular. There was a faint systolic murmur over the whole precordium, and a greatly accentuated second sound over the aortic cartilage. A diastolic murmur could also be heard, traceable down the sternum and audible in the back. The arteries pulsated vigorously; the pulse showed the Corrigan type. He improved slightly, but then dropsy occurred and he died. At autopsy it was found that the aorta was moderately dilated at its commencement, then became contracted at the origin of the innominate artery; this contraction increased until a point just beyond the origin of the subclavian artery, where it was totally occluded. Beyond this point the thoracic and abdominal aorta was thin-walled, but otherwise healthy. The aortic valve had 2 cusps. The anastomotic circulation had been carried out chiefly by the internal mammary and first 4 intercostal arteries. The diagnosis in this case should be possible. There should be excessive pulsation in the arteries in the head and neck, diminished pulsation of the abdominal aorta, retardation of the femoral pulse, excessive enlargement and pulsation of the intercostal, scapular, mammary, epigastric, and other superficial arteries. A heaving impulse beneath the angle of the scapular has also been described. Altogether, **complete coarctation of the aorta** has only occurred in 14 cases. It is often associated with valvular and arterial anomalies. It usually occurs just beneath the subclavian artery. [J.S.]

8.—A case of **separation of the epiphyseal head of the femur** is reported occurring in a girl of 15. The cause

of the injury was a fall in the street. The patient was operated upon for the relief of lameness and pain, the head of the bone and much callus being removed. The result was in every way successful. [M.B.T.]

11.—Alexander reports a case of a woman of 25 who was admitted to the Liverpool Workhouse Hospital after she had been in labor 3 days and was beginning to show signs of exhaustion. On examination the os was found to be fully dilated, the membranes had ruptured, and the liquor amnii had all drained away. The head was presenting with one foot beside it and the cord was prolapsed and pulseless. The bony pelvis was contracted in all diameters and the vagina also was very dry and contracted, so much so that it was impossible to introduce 2 fingers without great force and much pain to the patient. The pains were feeble and the patient much exhausted and crying out for delivery. After a short but futile attempt to turn the child, it was delivered by cesarean section, having evidently been dead for some time. The mother made a good recovery. [W.K.]

1. Endothelioma of Bone, with many Metastases. FRANZ H. BRANDT.
2. Facial Neuritis, Associated with Unilateral Retroorbital Neuritis. WILLIAM M. LEZYNISKY.
3. Ruptured Urethra, with Report of Cases. NATHAN JACOBSON.
4. A Case of Congenital Ocular Defect (?). E. E. BLAAUW.
5. What the Law Requires of the Surgeon. DUDLEY S. REYNOLDS.
6. Mastoid Abscess; Recovery without Operation. JOSEPH D. HARRIGAN.
7. An Unusual Case of Meralgia Paresthetica with Intermittent Lameness (Claudication Intermittente—Type Charcot). ALFRED GORDON.

1.—Brandt reports an interesting case of **endothelioma**. The patient was a man, 58 years of age. The disease was quite rapid, lasting 8 months from the time of its appearance until the death of the patient. The primary growth was situated on the right arm in the region of the tuberosities of the humerus. At the postmortem the primary growth was found to involve the upper part of the humerus, reaching below the tuberosities, being $5\frac{1}{2}$ inches in length and 5 inches in breadth, and had caused complete destruction of the head and neck. During life the tumor was fluctuating and had a systolic bruit. The skin, muscles, and periosteum were not involved. Other organs showed numerous metastases. The pleura was dotted with a number of nodules, varying in size from that of a pea to a walnut. The lung was greatly involved, showing metastases of all sizes, from minute spots up to those of 3 inches in diameter. The larger tumor masses seemed to lie in the central part. The ribs were also involved, and in one to the extent of causing spontaneous fracture. A pedunculated nodule was found in the diaphragm. The liver was sparingly involved. While both kidneys showed metastases, the right organ was more intensely involved, being almost completely changed into tumor tissue. [G.B.W.]

2.—Lezynsky reports the case of a woman, aged 33 years, who suffered from **facial neuritis with unilateral retroorbital neuritis**. The optic nerve was in a condition of advanced atrophy. [J.M.S.]

3.—Jacobson reports four selected cases of **ruptured urethra**. He says that the laceration is, as a rule, subcutaneous. An early diagnosis is very necessary, as immediate relief to the condition is imperative, as urinary leakage is to be anticipated, and skin infections of the soft part averted. He says that the best method of treating these cases is to drain the bladder by perineal incision. He does not believe in suturing, nor in the wearing of a permanent catheter. He says that the continuous irrigation of the bladder through the perineal wound keeps the parts in good condition, and that nature builds up a new canal by repairing the break in the old one, after the granulation tissue has been covered in by mucous membrane growing from the several ends of the urethra. The surgeon should shape the canal by the daily passage of a full size curved sound into the bladder. [O.B.W.]

4.—In the case reported by Blaauw, all abductive power of the left eye was absent, the patient being absolutely incapable of following an image with this eye into the temporal part of the visual field. There were, besides this, a few minor defects in the eye. He said that the condition had lasted a long time, but was not sure whether it was congenital or acquired. [G.B.W.]

5.—Reynolds reviews the various circumstances or conditions under which the surgeon may be arrested for malpractice. [O.B.W.]

6.—Harrigan reports a case of **mastoid abscess** occurring in a child 7 years of age, and apparently following an attack of grip. It has been the decision of several physicians, all men of repute, that the patient was suffering from mastoid abscess, and urgently needed operation. The parents, however, objected, and it was decided to temporize. Treatment consisted in the introduction of peroxid of hydrogen (15%), and in syringing the ear with copious injections of hot water. Internal dry heat was also applied. One morning considerable pus was found on the removal of a flaxseed poultice. This was followed by relief in all the local symptoms, and the patient was ultimately discharged cured. [O.B.W.]

7.—Gordon reports the case of a man, aged 45 years, who had typhoid fever 4 years ago. During convalescence he began to suffer intense pain in the neighborhood of the fourth sternocostal articulation. On account of suppuration, operation was performed. At the same time pain appeared in the anteroexternal and posterior surfaces of the left thigh. The pain was present for 2 years, but after an interval of one year returned. Again it disappeared, until 17 weeks ago, when it reappeared. The patient had varicose veins, and at two different times resections of the internal saphenous vein, first on the leg, then on the thigh, were performed. The patient is distinctly neurasthenic. There is no syphilis or alcoholism. His family history shows that there is a strong neurotic element. The actual symptoms developed during the attack of typhoid fever. While seated and while walking the patient complains of a burning sensation over the anteroexternal surface of the upper two-thirds of the thigh. The whole paresthetic area is in isolated patches with intervals, and the tactile sensation over the diseased portion is very much diminished. The case is atypical because in addition to the anterior branch of the external cutaneous nerve, the posterior is also affected, one or two cutaneous branches of the anterior crural nerve are involved, and there is a phenomenon called **intermittent lameness**. The external cutaneous nerve is placed in a muscle indispensable to standing and walking (the psoas) and in connective tissue (fascia lata), the contraction of which in walking presses upon it and stretches it. The musculoponeurotic relation and the superficial position of the nerve expose it to traumatic injuries, especially in individuals predisposed to painful paresthesias. A slight neuritis, that perhaps would remain latent in any other territory of the nervous system, is marked in the sphere of the anterior branch of the external cutaneous nerve. [J.M.S.]

Medical Record.

November 10, 1900. [Vol. 53, No. 19.]

1. Some Clinical Aspects of Gout. BEVERLY ROBINSON.
2. The Relief of Prostatic Enlargement. JOSEPH B. BISSELL.
3. The Constant Quantity in the Various Climatic Treatments of Tuberculosis. C. G. CAMPBELL.
4. Chronic Copper Poisoning Among Artisans. HENRY A. KURTH.

1.—Robinson believes that no especial form of diet is always useful in **gout**. Some cases will do well on strictly "anti-gout" diet, while others will show better results from a diet that contains articles usually thought to be especially bad for gouty subjects. He considers that no case of relapsing appendicitis should be operated upon until there has been treatment used against a possible gouty or rheumatic condition, and gives brief accounts of cases to show that throat, ear, and skin troubles, and other affections that have resisted other treatment may subside upon the use of treatment directed toward the improvement of such diatheses. [D.L.E.]

2.—Bissell discusses in a thorough manner the various procedures which have been used for the relief of **prostatic hypertrophy**. Among the various radical operations which have been proposed he favors perineal prostatectomy by the lateral incision. He considers perineal prostatectomy with drainage an operation—in competent hands—no more dangerous to life than an interval operation for appendicitis, provided cases are properly selected, in which degeneration of the general and special tissues of the body has not gone on to a hopeless extent, in which the bladder and kidneys are not too seriously damaged, and in which septic infection, if present, is not too profound. But, even under part or all of these adverse conditions, complete removal of the prostate with free drainage is the rational and scientific method of radical treatment, and offers the best hope of relief, and the most favorable chance for a permanent cure, with the least danger to life. [M.B.T.]

3.—Campbell considers that the constant factor active for good in various climates favorable to **tuberculous subjects** is the prevention of reinfection. There should always be measures taken for disinfection of the sputum and the like in tuberculous patients where they must be treated at home, in order that so far as possible the lack of proper climatic conditions may be offset by such measures. [D.L.E.]

4.—There is much question whether **chronic copper poisoning** really exists as a definite condition (see recent abstract of Lewis's article from *Deutsche medicinische Wochenschrift*). Kurth believes that it does. The symptoms which he describes are chiefly those of irritation of the gastrointestinal and other mucous membranes. Anemia with a sallow color, extreme nervousness or restlessness, and greenish discoloration of the hair and teeth. [None of these is characteristic of any special intoxication. The discolorations are merely stains]. The treatment is chiefly prophylaxis and change of occupation. Strychnia is a good tonic. [D.L.E.]

Medical News.

November 10, 1900. [Vol. lxxvii, No. 19.]

1. Some Observations on Anesthesia by Intraspinal Injections of Cocain. S. ORMOND GOLDAN.
2. Further Experience with Subarachnoidean Injections of Cocain for Analgesia in all Operations Below the Diaphragm. JOHN B. MURPHY.
3. The Examination of Stomach-Contents. W. A. BASTEDO.
4. The Hydratric Treatment of Tuberculosis. J. H. KELLOGG.
5. Bronchial Anesthesia Not Invariably a Contraindication for Ether Anesthesia in Abdominal Surgery. THADDEUS A. REAMY.

1.—Goldan says that **anesthesia by intraspinal injections of cocain** is not superior in safety or in advantages to ether, chloroform, or nitrous oxid. He sums up the deductions of his own experience and of others as follows: Cocain introduced into the subarachnoid space acts in the same way as when injected into the general circulation, being possibly less toxic. There is no definite quantity which will answer in all cases. The degree of action of the drug does not seem to depend on any apparent individuality of the patient, and there is no method of determining how any particular dose will act in a particular case. Therefore large doses should never be used until the individual susceptibility is determined. He says the place for intraspinal cocainization is at the end of the list of anesthetics, when speaking of its general practicability. In individual cases, when chloroform, ether or nitrous oxid are contraindicated, the use of cocain injected into the spine is often of great service, and in this way is a useful addition to the armamentarium of surgery. [G.B.W.]

2.—Murphy says that the danger of **failure in the technic** regarding the use of **subarachnoid injections of cocain** are due either to the fact that the cocain solution is not fresh, or that the needle escapes from beneath the dura, or is forced through the dura in making connections with the barrel of the needle. In the two latter events, the fluid would escape in front or behind the dura, and no analgesic effect could follow. He says that in minor operations upon the foot, leg, knee, and hip, 10 m. of a 2% solution will be sufficient. It is best that the syringe should have a slide

and not a screw connection, as a twist of the barrel is likely to dislodge the tip of the needle from the dura. Cocain has decided advantages in cases of intestinal obstruction, first, the patient is quickly prepared for operation; second, the danger of inhalation-pneumonia is nil, a matter of great importance; third, the prolonged depression so general in this operation from general anesthesia is avoided. [G.B.W.]

3.—Bastedo gives a brief account of some of the **simpler methods** by which the **gastric contents** may be **analyzed**. He advises for a test breakfast, a good dry hard breakfast roll without butter, and 12 ounces of water. For estimating the free HCl he recommends dimethylamidoazo-benzol. He adds a few drops of this to 5 cc. of the filtered contents bitrates with and decinormal NaOH; he then adds a few drops of congo red, and determines the quantity of free organic acids in the same manner. Finally he adds a few drops of phenolphthalein and determines the combined acids. This, of course, is a modified Tuffier method. He also gives the usual tests for blood, lactic acid, etc., and a few simple directions regarding treatment. [The author fails, apparently, to take into account the different points in the scale of alkalinity, at which the indicators that he employs react. This, of course, interpolates a small error into the results. J.S.]

4.—Kellogg, in discussing the **treatment of tuberculosis**, calls attention to the fact that at present it is impossible to destroy the tubercle-bacilli in the lung. Even if it were possible there would be every likelihood of the recommencement of the disease in the damaged tissue. The open-air treatment is probably the most efficient, but a method of considerable value is the application of cold in the form of moisture to the skin. This stimulates the vasomotors, and may be considered as a form of vasomotor gymnastics. The three methods suggested by Aberg consist of cold sponging to the head, neck, back, and chest, cold douching of the same parts, and a full cold bath for from 2 to 6 seconds. Kellogg suggests the following methods: Dry friction either with the hand or mitten, followed by friction with the water at 60°; cold wet friction, commencing at 60° F. and gradually decreasing, and finally, the wet sheet which is wrapped around the patient whilst he is being vigorously rubbed. The initial temperature of this should be about 60°, and subsequently it may be decreased to 50°. The entire application should not last for more than 2 or 3 minutes. Sometimes it is more efficient if preceded by heat, such as sun-baths, dry friction, or vapor baths. Another method is a warm rain douche; the water being at 100° F., while hot sprays of higher temperature are applied to the legs. [J.S.]

5.—Reamy is convinced that **ether is a much safer anesthetic than chloroform**, and should be selected in all cases, except in the presence of strongly-marked contraindications, as in serious disease of the kidneys or respiratory organs. He says that his clinical studies justify him in the belief that in properly selected cases, ether-inhalation is positively curative of bronchitis. To avoid any unpleasant complications and to secure the desired results, the following points in etherization are essential: (1) Proper preparation of the patient; (2) preparation of the operating-room with the temperature of 98° to 100° F.; (3) pure ether; (4) the proper inhaler; (5) the proper methods of administration; (6) due caution against exposure in removing the patient from the operation-room to her own room; (7) proper care of the patient during convalescence. [G.B.W.]

Boston Medical and Surgical Journal.

November 8, 1900. [Vol. cxliii, No. 19.]

1. A New Test Meal. A. E. AUSTIN.
2. Spinal Caries with Abscess: Analysis of Cases. ERNEST B. YOUNG.
3. Celluloid as a Material for Flat-Foot Supports. ALBERT H. FREIBERG.
4. The Agglutination by the Patient's Serum of the Bacteria Found in Cystitis and Pyelitis, with a Consideration of the Pleomorphism of the Bacteria Found in these Infections, Especially as Regards Chromogenic Properties of the Staphylococci. THOMAS R. BROWN.
5. The Management of Abdominal Testicular Ectopia Associated with Inguinal Hernia. CHARLES A. POWERS.

1.—Austin has devised a new test-meal for exact work, which consists of 2 grams of dried egg albumen in the form of tablets, and 2 glasses of water. This has the advantage of being liquid, so that solid masses never clog the tube; the contents filter readily, and lactic acid, when found, is of much more diagnostic importance. Moreover, it is very conveniently administered, and of practically invariable strength. The disadvantage is that starch digestion cannot be determined. A number of tests, amounting in all to 73 examinations upon 34 patients, were made. Usually Ewald's breakfast was employed alternately with the albumen, and the results in both cases were remarkably similar. Austin gives a number of interesting data concerning some of these individual examinations, which we cannot repeat. It is remarkable how frequently lactic acid was present as determined by a modified Uffelmann's test; altogether 40 times in 9 cases without free HCl, in other cases when free HCl was present in the proportion of 1.8 per mille. Renin was also determined in the majority of cases. The stomach contents were diluted in various proportions, and then an equal quantity of boiled and cooled milk, and a small amount of calcium chlorid solution was added. Coagulation usually occurred in dilutions of 1 to 80 or higher, in less than a half an hour. Austin believes that lactic acid is of little value as a diagnostic symptom, for it is often present when there is a superabundance of HCl. [Our own results have been so at variance with those of the author that we feel certain there must be some serious error in technic in our work or in his. J.S.]

2.—Young has collected 78 cases of spinal caries complicated with abscess, and has obtained reports from the condition of the patients living at periods of from 1 to 35 years after the beginning of the disease. The condition seems to be about twice as frequent among males, 52 males and 26 females being affected. From 20 to 30 years of age, however, the males outnumber the females nearly 5 to 1. The dorsal region was the seat of disease in 43 cases, the lumbar region in 31, the sacral region in 2, and the cervical region in 1 case. Deformity was present in 30 cases, no deformity in 18 cases, medium deformity in 16 cases, and great deformity in 13 cases. Abscess formation seems to have little relation to the extent of deformity. Psoas abscess was found in 63 cases, lumbar abscess in 21, sacral abscess in 2 cases, and cervical abscess in 1. It is impossible to get reliable information concerning the duration of abscess or the date of first appearance. Pain becomes a prominent feature only when the abscess has reached a size to produce psoas contraction. Most of the patients were treated by incision, some by aspiration, and in a few cases the abscess opened spontaneously. The prognosis appears to be very slightly influenced by the treatment. The mortality is about 35%. There seems to be decided danger of general tuberculous invasion, and in both children and adults the most common cause of death seems to be gradual deterioration in the whole system. [M.B.T.]

3.—Freiberg states that the use of celluloid as a material for flat-foot supports was first suggested by Kirsch. Its advantages are lightness, absence of tendency to corrode, cleanliness and elasticity. It is less durable than steel, however. The plates may be made by taking an impression of the foot upon cardboard and from this paper pattern another is cut in sheet lead. The sheet lead pattern is then moulded to the shape of the foot. The celluloid is cut out in the proper shape and fastened to the lead pattern with clips. It is then lowered into boiling water and as soon as it has begun to soften is pressed down to the pattern and moulded into shape. The plate is then immersed in cold water for a few minutes and is then ready to apply. [M.B.T.]

4.—Brown has obtained microorganisms from the urine in various cases of cystitis, and tested them with the patient's blood, for the purpose of determining whether the reaction of agglutination was present. In the first case the colon-bacillus was found in the urine, and reacted within 10 minutes; in the second case the infectious organism was the proteus vulgaris; in the third, the same organism caused cystitis and pyelitis; in the fourth, the typhoid-bacillus was found and reacted positively, although the patient did not have, and apparently had not had, typhoid fever. It is possible that the infection was due to catheterization. The commonest cause of cystitis is the colon-bacillus. Among the other microorganisms are staphylococci, tubercle-bacilli, and those already mentioned. [J.S.]

9.—Knox reports the case of a young woman of 20, who was affected with lupus of the nose and upper lip which had progressed so far as to produce perforation of the nasal septum. She was treated by application of x-rays for from 6 to 10 minutes every other day, placing the affected parts from 4 to 8 inches from the tube. The whole number of applications made during the treatment was 74, and improvement was apparent very soon after beginning the treatment. The unaffected parts of the face and head were shielded by means of a mask, thus preventing the possibility of producing dermatitis and loss of hair. A photograph taken since the x-ray treatment shows almost entire absence of scars, or any condition of the tissues that would indicate that the disease had ever existed. [M.B.T.]

2.— " " " " " " " 995.

5.— " " " " " " " 9-5.

6.—Mundell reports 3 cases of tuberculosis of the wrist-joint, the pathologic conditions in which led him to consider the os magnum the bone chiefly concerned in the development of the disease. The reasons for this are probably that the os magnum is the main bone of the wrist, the earliest to ossify and is so situated as to receive the effects of injuries from 3 metacarpal bones. It performs more movement in flexion and extension than any other bones and in these movements greater strain is thrown on it than on any other carpal bones from the numerous ligaments connected with it and resisting such movements. The cancellated structure of the os magnum is uneven, the inner portion has wider spaces and is less strong. Vibrations from traumatism affect the os magnum more than the other carpal bones, and it is probable that tubercle-bacilli from the blood or lymph would

be more prone to concentrate there. In the treatment of these cases he prefers Ollier's method. Instead of removing the carpus entire the neck of the os magnum is divided so as to permit freer access to the semilunar and scaphoid bones which with the other bones are easily removed with the assistance of a dental stump elevator. [M.B.T.]

7.—Binnie calls attention to the fact that in **excising the shoulder-joint** the principal difficulty is in the separation of the tendinous insertions into the major and minor tuberosities of the humerus. In cases of disease of the hip and ankle-joint König has overcome similar difficulties by chiseling a shell of bone from the trochanter major or malleoli. This has much to recommend it on account of its simplicity, and Binnie advises a similar operation for the shoulder-joint, the steps of which are described. [M.B.T.]

8.—Elder reports a case of **strangulated obturator hernia**, occurring in a woman of 73. Three days previous to the time when first seen she received a sudden jar by missing a step. This was followed by severe pain in the lower part of the abdomen, shooting down the right thigh of the knee. She became nauseated and vomited, the vomitus having a fecal character. There was decided abdominal distention and obstinate constipation. As a definite diagnosis as to the cause of the obstruction was impossible, an exploratory median incision was made below the umbilicus. The intestine was deeply injected, but there was no evidence of peritonitis. Collapsed small bowel was seen, which was followed down into the pelvis behind the right pubic ramus. This intestine was tightly grasped at the upper part of the obturator foramen. This distended bowel was traced to the same spot. By pulling on the ends of the bowel it was disengaged with some difficulty. The strangulated knuckle was black and occupied three-fourths of the circumference of the bowel. Hot towels were applied which restored the circulation, and the bowel was dropped back into the abdomen. No attempt was made to close the obturator opening. The abdominal cavity was filled with salt-solution and closed without drainage. Uninterrupted recovery followed. [M.B.T.]

9.—Hull reports a case of **backward dislocation of the bones of the knee**, caused by falling from a horse and alighting on the feet. Prolonged attempts were made at reduction without success, and 8 months after the injury, resection of the knee-joint was performed. [M.B.T.]

5. Uretero-Intestinal Anastomosis and Its Place in Pelvic Surgery. REUBEN PETERSON.

1.—Robinson holds that the testimony in favor of the production of **reflex neurosis from dislocated genitals** is ample for the gynecologist. Distorted mechanism of the pelvic structures causes genital dislocation. Dislocation of structures compromises circulation by the strangulation of vessels and thus induces malnutrition. Dislocation of structures causes trauma to nerve-trunks and nerve-periphery, causing pain and reflexes which radiate over nerve-tracts to other viscera and there disturb motion, secretion and sensation. Tension placed on a woman through dislocated genitals, by compromising circulation and by trauma of nerve-periphery, devitalizes her system and exposes her to intercurrent disease and to the great functional neuroses (neurasthenia and hysteria). Menstruation is a vascular periodic wave and belongs to the uterus and oviducts, not to the ovary; hence, menstrual neuroses are cured by removal of the menstrual organ, and not by removal of the ovary. It is an error to perform castration because the menstrual process coincides with the neurosis. In such a case, should an operation be performed, it ought to be hysterectomy and not ovariectomy; the organ which induced the neurosis should be attacked. In the diagnosis one must observe local diseases in the body which are not of sexual origin.

The sexual organs are not the only viscera capable of producing neurosis. We should be always on the alert for visceral ptosis, tuberculosis, nephritis, and appendicitis. The non-sexual disease may be coincident with sexual diseases, and both influence the neurosis and general nourishment. We should make careful examinations for diseases outside the genitals; and should not overlook heart lesions, which allow congestions; hepatic sclerosis which induces ascites; chlorosis which induces paleness, with a large glandular system, yet coexists with a well-developed panniculus adiposus, headache, and breathlessness, anemia, etc. In the author's experience nothing has been so successful as draining the skin by salt baths, the kidneys by drinking ample fluids, and the bowels by salines, with set hour for evacuation. Drainage of the bowels, skin, and kidneys is the base of the therapeutics which will benefit the vicious sexual circle. It is rational hydrotherapy. Thus, by treatment, we are often enabled to run over one difficulty after another until the etiologic factor is reached, which is disturbed pelvic mechanism, the beginning of the vicious sexual circle. In other words, the microscope aids to diagnose tuberculosis, or mercury to diagnose syphilis. In diagnosis and treatment the gynecologists must always hold in his mental grasp every abdominal organ. [W.K.]

2.—According to Ill the causes of **inflammation of the pelvic peritoneum** are: infectious diseases and traumatism. Under the first we have to consider gonorrhea as by far the most frequent. While an infection of purely gonococcus origin is thought rarely to produce an extensive peritonitic inflammation or abscess, a mixed infection, *i. e.*, gonococcus with streptococcus or staphylococcus, will commonly produce such, and is often the cause of a fatal peritonitis. There is no doubt that the mixed infection is more frequently a so-called secondary infection by pyogenic bacteria. The gonococcus seldom, if ever, affects the cellular tissue. There is no doubt, however, that it may pass through the tissue of the tubes, probably, for instance, by way of the lymphatic channels, and infect the peritoneal covering. Among the most frequent causes of traumatism are the rupture of the fallopian tube containing a growing ovum, an extraperitoneal hematocoele, a disturbance in the circulation of an ovarian or uterine tumor by torsion or otherwise, an intraperitoneal hemorrhage not due to ectopic pregnancy, and, lastly, the leaving of large raw surfaces denuded of peritoneum after intraabdominal operations. Extensive traumatism after labor, with opening of the pelvic peritoneum and secondary infection should not be forgotten. Ill considers medical treatment only, and says our aim should be to conserve the pelvic organs of the woman so long as there is hope of a subjective cure. In treating an acute gonorrheal case, the patient should be kept quietly in bed, the bowels thoroughly emptied by a saline cathartic or one of the bitter waters. This should be repeated every second day. The diet should be a bland and liquid one so long as the temperature is above 101°. The pain is most readily controlled by an icebag placed over the hypogastrium. It is not wise to prolong the application of the icebag, as the writer has seen a slough follow its long-continued use. Nor does the patient bear it well when her temperature has fallen below 101°. The vagina should be douched with hot permanganate of potash solution (1 to 2,000 of water) several times daily. When the discharge is very copious it is sometimes wise to fill the vagina with iodoform gauze. When the fever has abated, but the pain still continues, nothing will relieve it so much as a fly-blister 1 by 2 inches square, placed directly over the pain. When the swelling in the roof of the vagina is very great with sensitiveness to the touch, apply cantharidal collodion around the cervix, covering it with dry cotton with directions to remove it in 4 hours. A very copious purulent discharge follows, which lasts 2 or 3 days and should be washed away with douches several times a day. This should be followed with daily applications of a 10% solution of ichthyol in glycerin, the tampons being applied in the evening and removed in the morning. The blisters, both external and internal, may be resumed in from 5 to 8 days. The relief they give is so great that the patient rarely objects to their use. In chronic cases we may begin by painting the roof of the vagina with the compound tincture of iodine and applying the glycerin-ichthyol tampon. During the 2 days following the removal of the tampons the patient should

be directed to take a large, hot vaginal douche night and morning, preferably in the knee-elbow position. In these cases much good has resulted, in the hands of the writer and his assistants, from the Thur Brant method of pelvic massage. It consists of treating these chronic cases, *i. e.*, the adhesions and chronic thickening of the tubes, uterus and broad ligaments, by systematic massage. [W.K.]

3.—The object of Will in this paper is, in the first place, to add a mite of personal testimony in maintaining the theory that the female ovary furnishes a product concerned in modifying the tissue-forming processes of the general system during the mid-period of life and more markedly of the tissue anabolism of the generative organs themselves; and, in the second place, to assist in formulating a course of treatment in consonance with this view and more directly and specifically efficient in correcting the constant aberrations of structure and function. [W.K.]

4.—Rennotte reports a case of ventral hernia which was instructive in these points: First, the resistance of catgut sutures; second, the prompt efficiency of carbolic acid in gum camphor in killing the staphylococci and inhibiting the progress of the infection; third, the good results from free injection of the fistula with normal salt-solution followed by 1% carbolic acid solution. [W.K.]

5.—The advocates of uretero-intestinal anastomosis claim that the urinary and digestive tracts below the pelvic brim may be united permanently in 3 ways: (1) The ureters severed from the bladder may be anastomosed with certain portions of the intestinal tract, preferably some segment of the large bowel; (2) the anastomosis may be accomplished by implanting in the intestine the vesical trigonum with its ureteral orifices; and (3) the ureter-intestinal union may be established by the formation of a permanent communication between bladder and rectum in the male, and between bladder, vagina and rectum in the female. But Peterson fails to understand how anyone can see any place whatever for the operation of bilateral ureteral implantation in human surgery, if his opinion be based upon experimental results, which may be summarized as follows: (1) The vast majority of the animals operated upon die from the operation itself, either from acute general peritonitis or an acute septic nephritis; (2) the animals surviving the operation usually die from an acute ascending pyelonephritis, or from pyemia from secondary infection; (3) in a very few instances they overcome the infection and survive, with resulting contracted kidneys; and (4) as one could expect, when a small compressible tube like the ureter is implanted in a large muscular tube like the intestine, contraction at the uretero-intestinal junction results, to be followed by dilation of the ureter and hydronephrosis. He has been able to collect 33 cases of uretero-intestinal implantation, with a primary mortality of 37%. If to these be added the cases dying later of kidney infection, the mortality would be increased to 52%—not a promising mortality for these days of aseptic surgery. [W.K.]

7. The Recumbent Position in the Treatment of Abnormalities in the Form, Shape, and Size of the Uterus. BECKERS.

1.—Killing says that pneumonia is the most dangerous of the complications which follow operations on the gastrointestinal canal. The causes ordinarily assigned as responsible for the development of the postoperative pneumonias are: (1) The inspiration during the narcosis of putrid secretions or contents of the stomach; (2) the lodging of emboli in the vessels of the lung; (3) the continued dorsal position while the resistive powers of the patient are at an extremely low ebb, causing a hypostatic congestion,

and (4) the ordinary infective processes causing a pneumonia in the sick just as well as in a well person. To this last class belong cases in which the inflammatory condition of the lung comes on directly after the operation without any assignable reason, the first symptoms being manifested within 24 hours. Here it is most probable that the patient was infected during the operation in some way or other. Killing says that the etiology of these cases is dependent on the admission of air to the abdominal cavity so that it strikes against the under surface of the diaphragm, allowing numerous bacteria to accumulate there and be carried by the lymphatics through the diaphragm to the lungs. This explanation is substantiated by the fact that since his operating-room has been so constructed as to provide for practically germ-proof air he has not had a single case of unexplainable pneumonia. [G.B.W.]

2.—Peters believes that the operation of shortening the round ligaments for the reduction of the retroflexed uterus, discovered almost simultaneously by Alexander and Adams, is an extremely valuable measure when used in suitable cases. It is only applicable when the uterus is mobile, and in no way affects the utility of the various other operations on cases where this procedure is not preferable. He reviews the literature relating to this operation and describes the method of performing it used in the Kiel clinic where he was a resident for a long time. [W.K.]

3.—Muck has been able to demonstrate the presence of potassium sulfoeyanid in the nasal and conjunctival secretions. Its presence in the saliva has, of course, been known for a long time. He uses both the ordinary reaction with chlorid of iron and dilute hydrochloric acid, and one discovered by Solera, which is performed as follows: Chemically pure filter paper is saturated with a concentrated solution of iodic acid, dilute sulphuric acid, and starch paste. After the water has evaporated the strips are introduced into the nose, and are then colored blue if potassium sulfoeyanid is present in the watery secretion. The mucus of the nose does not give the reaction. The secretion of the conjunctiva also reacts, and the author was able to prove that the potassium sulfoeyanid in the nasal secretion does not come from the conjunctiva. [D.R.]

4.—A number of experiments were made to determine the possibility of general infection when the conjunctival sac is the portal of entry. The author employed the organisms of anthrax, plague, psittacosis, chicken cholera, mouse typhus, tetanus, diphtheria, Staphylococcus pyogenes, cholera, typhoid fever, actinomycosis, tuberculosis, glanders, and pseudotuberculosis. The result in a majority of cases was a general, fatal infection of the body of the animal through entrance of the bacteria into the circulatory stream. This occurred rapidly in anthrax, plague, chicken cholera and mouse typhus, and in glanders and psittacosis; more slowly in pseudotuberculosis; and chronically in young animals in psittacosis and glanders, and in tuberculosis. Tetanus and diphtheria were fatal by intoxication. In diphtheria and Staphylococcus pyogenes local infections were produced. Cholera, typhoid, and actinomycosis were unable to penetrate into the organism. The course taken by the bacteria is as follows: They enter the lacrimal canals and thence pass into the lacrimal sac. Here there is a transient arrest favoring multiplication of the bacteria, and from the sac they are able to penetrate into the deeper tissues. A similar arrest and penetration occur in the lacrimal duct, on account of its folds and valves. From the canal the process may extend to the nasal cavities. The bacteria in their wanderings from the lacrimal sac enter the lymph-capillaries. There was no evidence of any retrograde transportation of the bacteria along lymph-capillaries. With the lymph they passed into the lymph-glands, particularly those of the neck on the side of the inoculation. This constituted a primary lymphogenic infection of the lymph glands. Later a secondary hematogenic infection of the glands was also produced. [D.R.]

5.—Iodipin is a combination of iodine and fat containing 25% of the former. It is useful in tertiary syphilis and other affections in which potassium iodid is generally employed, and has the advantage that it is borne when the latter is not tolerated. It can also be used subcutaneously, and as its elimination is slow, the iodine effect persists longer. Administered by the mouth, it may be given in coffee or milk. The dose is from 2 to 3 teaspoonfuls a day. [D.R.]

6.—After studying the wonderful effect of sugar upon wearied muscles, as shown in the work of Payer, Madlener conducted a series of experiments with it in obstetric cases. He found that labor-pains were much accelerated and strengthened by its use. After the beginning of labor he had always, by the patient's side, water or tea strongly sweetened, which was administered at intervals during the confinement. He believes that it is likely to be a valuable aid to the obstetrician and says it can at least do no harm. [W.K.]

7.—Beckers believes that the **recumbent position**, habitual in sleep and during illness and the **lying-in period**, is responsible for many malpositions of the uterus. He advises women to sleep directly upon the abdomen, and particularly to use this position during the puerperium, as he believes the uterus will thus much more rapidly regain its normal size and position. [W.K.]

10. Traumatic Tetanus Through Stoppage of the Bowels. (Laparotomy; Recovery Without Serum-Injection.) KREY and SARAUW.
11. The Treatment of Tetanus With Antitoxin. REUTER.

1.—A brief resume concerning the present status of **immunity**, in which Buchner shows that neither the phagocytic nor the humeral theory is a sufficient explanation of the phenomena, but that both are in part correct. The protective bodies normally present (the alexins) are probably the result of secretion by the leukocytes. Specific immunity is dependent upon specific bodies characterized by their resistance to a temperature of 60° C. There is a multiplicity of names for these specific bodies. Buchner proposes a greater uniformity of nomenclature and suggests that these substances in general be called **antikörper** (antibodies), and their varieties, **antitoxins**, **antithematis**, etc. [D.R.]

2.—Further study with the **tonometer** (an instrument for measuring blood-pressure in the living body) has led Gaertner to the conclusion that the tonometric values correspond quite closely to the absolute values of the average blood-pressure, and that the variations in the readings shown by one and the same individual are indicative of corresponding variations in the actual pressure. [D.R.]

3.—The **diazo reaction** in the urine in phthisical cases has been looked upon as a bad prognostic omen. Becker has applied the test to 29 patients, and concludes that a positive reaction is not always a bad prognostic sign. The occurrence of a positive reaction in conditions in which it is usually absent is indicative of an infectious complication. In 2 cases of the author's there was chickenpox in one and a staphylococcosis in the other. [D.R.]

4.—**Osteomyelitis of the vertebral column** is rare, especially that involving the **atlas**. Four cases of disease of the latter have been reported, to which the author now adds one of his own. In the other 4 there were large collections of pus in the neighborhood of the vertebrae, which had destroyed the musculature and had penetrated through the tissue up to the skin. A collection of pus in the posterior wall of the pharynx, which theoretically is possible and is common in tuberculosis of the vertebrae, was not present. In 3 cases the pus was evacuated, but in none was the bony focus of disease found. Bacteriologic examination was made only in the author's case, and yielded the *Staphylococcus aureus*. The **portal of entry** for the bacteria in osteomyelitis of the vertebral column is but seldom found. In 6 cases there was a trauma. In 1, a case of osteomyelitis of the base of the skull, a furuncle on the lower lip seemed to

be the infective atrium. The clinical features are twofold. In one group of cases the disease sets in under the picture of a **grave general infection**, with high fever, delirium, and hebetude. A diagnosis is scarcely possible. Such cases have been diagnosed as cerebrospinal meningitis, typhoid fever, or cryptogenic sepsis. Even when spinal symptoms are present, they may be misleading. Thus, there have been paraplegia and paralysis of the bladder and rectum, which are suggestive of Landry's palsy. When the pus passes along the anterior surface of the spinal column, it may lead to a posterior mediastinitis, and finally to a psoas abscess. In its passage along the anterior surface of the spine the pus may penetrate into the chest or abdominal cavity. In other cases the disease begins with **local symptoms** chiefly. This happened in the author's patient. The abscesses in these cases have often produced difficulty in swallowing and breathing, and have led to inspection and palpation of the pharynx, although in osteomyelitis of the atlas the pus seems, as a rule, to burrow toward the back of the neck rather than toward the throat. The author's patient was a soldier of 27, whose first complaint was pain in the neck, which was intensified by sitting up or going down stairs. A few days later the neck became stiff and swallowing was somewhat difficult. There was mild fever; the head was slightly flexed and turned toward the right, and active movement of it was impossible. At the right side of the neck there was a swelling, beginning a little below the mastoid process and extending halfway down. It did not extend beyond the median line behind, and reached forward to the posterior border of the sternocleidomastoid muscle. Under chloroform anesthesia the abscess was opened and was found to be situated beneath the sternocleidomastoid and trapezius muscles. The right side of the arch of the atlas was destroyed, and 2 sequestra were removed. Culturally the pus contained *Staphylococcus aureus*. The patient made a complete recovery. Another case is reported in which there was **osteomyelitis of the base of the skull**. In this condition the abscess is usually located at the lowest part of the skull, directly beneath the superior occipital line. The patient was a sergeant, 26 years old, who had a boil on the right lower lip at the beginning of December. At the end of December he complained of tearing pains over the right eye, radiating to the ear, and worse at night. They gradually became more intense and extended more widely. Fever developed. There was no paralysis. Movement of the head was somewhat limited, and there was a doughy swelling beneath the superior occipital line. Operation revealed an abscess, and at its bottom the roughened bone could be felt. After the discharge of some sequestra, the patient recovered. The first symptom in this patient was pain in the distribution of the right supraorbital nerve, which was treated as neuralgia of obscure origin. This pain was probably transmitted by way of the occipitalis major and minor and auriculotemporal nerves. The diagnosis of **osteomyelitis of the atlas** can be made if, with or without preceding neuralgia, a limitation in movement of the cervical vertebrae develops, with localized pain. Whether the disease is osteomyelitis or tuberculosis is not easily determined. Radical operation is discountenanced by von Bergmann in tuberculous disease, but Eichel advises an early operation, so as to prevent involvement of the spinal cord and its membranes. In cases in which the symptoms suggest osteomyelitis he would operate, even in the absence of fluctuation, so as to remove the danger of extension to the spinal canal. If tuberculous lesions were then found, he would tampon the wound and depend upon fixation and rest in bed. [D.R.]

5.—Rosenfeld believes that the **normal position of the stomach** in human beings is **vertical**. In 167 cases he found only 12 in which the position was horizontal. [D.R.]

6.—Spaeth questions the correctness of the dictum of Dührssen, that after the introduction of an iodoform-gauze tampon the uterus will contract satisfactorily. In his own experience he has known cases in which, after the use of such a tampon, the hemorrhage has recurred and the relaxed condition continued, making other remedies necessary. Other authors have reported cases in which infection has resulted from the use of tampons to control hemorrhage. Hence, Spaeth concludes that one is not justified in considering the iodoform-gauze tampon as an unfailing remedy for

atonic postpartum hemorrhage. Moreover, if it appear effective for a moment, the patient requires a longer observation, since a return of the hemorrhage is not entirely excluded. [W.K.]

7.—Heil reports a case of **emphysema** of the skin following the removal of the uterus and adnexa. The emphysema was first noticed on the fifth day after the operation and was then very extensive, spreading in both directions from the line of incision. The healing of the wound was not disturbed by the emphysematous condition, being firmly united in 14 days. The emphysema was gradually absorbed without any special trouble. The air supposedly gained entrance to the tissues through the wound and this because there was not an absolute approximation of the different layers of the abdominal wall. [G.B.W.]

8.—A case of transverse presentation is reported by Jacob, who, after version, delivered the feet and limbs, when spasmodic contractions of the uterus prevented further progress. As circumstances made a complete bath impossible, hot, wet clothes were applied to the uterus for 1½ hours, when the tetanus disappeared and delivery was completed. The retained placenta was removed manually; vigorous massage and a drawing downward of the cervix with Muzaux forceps produced proper contractions of the relaxed uterus and checked the hemorrhage. Jacob has nowhere seen mention of the application of hot, wet cloths as a remedy for tetanus and thinks it worthy of trial. [W.K.]

9.—The joint complications in this case of **ophthalmia neonatorum** began as the eye was getting better. Both knees were affected, but the right one recovered without suppurating. The left knee, however, did suppurate and was operated on. The joint capsule was thickened and the synovial membrane velvety and thrown into folds over the joint cartilages. The joint was irrigated with lysol and normal salt-solution and the patient made a good recovery, though with a slightly stiff knee. [G.B.W.]

11.—In a case of **tetanus** with an incubation period of 16 days, **antitoxic** treatment was of **no avail**. [D.R.]

Deutsche medizinische Wochenschrift.

1. A Group of Cases with Disease of the Upper-Air Passages, belonging together Clinically and Etiologically. ERNEST NEISSER and KAHNERT.
2. Symptomatology and Diagnosis of Membranous Colitis. J. BOAS.
3. A Particular Symptom-form of Carcinoma of the Stomach, together with a Discussion of Atony of the Esophagus. R. SCHÜTZ.
4. Does Alcohol Act as a Food or as a Poison? KASSOWITZ.

1.—Five cases are reported in which the following facts were observed: All had **chronic trouble with the upper air-passages** which had lasted for years, always most severe in winter and showing marked summer remissions. They all showed atrophy of the mucous membrane of the nasopharynx, the pharynx, larynx, and even of the trachea and to some extent of the nose. The follicles were swollen; there was excessive secretion of mucus, but no formation of scars or adhesions. There was therefore no evidence of rhinoscleroma and the organism of this disease was absent. The cases had the characteristics of **ozena**, but syphilis and bone deformities were absent and Abel's bacillus could not be found. Bacilli which had the characteristics of the diphtheria bacillus were present in each case, however; they were virulent in only 2 instances, but the blood-serum of the other 3 patients was found to contain so much antitoxin as to protect animals against large doses of diphtheria toxin. The bacilli also showed agglutination reaction with the serum of a goat infected with diphtheria. There was no formation of pseudomembrane and no clinical appearance of diphtheria, but it seemed hardly possible that the process was due to the diphtheria bacillus. Attempts to increase the immunity of the subjects by giving diphtheria toxins could be tried in but one case. The injections caused pain and local infiltration, but improvement ensued. This was just at the beginning of warm weather, however, and the improvement may have been the usual summer remission. [D.L.E.]

2.—Boas defines **membranous colitis** as a peculiar

catarrhal affection of the colon accompanied by formation of mucous casts and always associated with some actual disease. Mucous colic, on the other hand, is characterized by colicky attacks, passage of mucous casts and *absence* of local disease. The latter is much the rarer and can be diagnosed only when mucus is regularly absent from the stools in the interval and other signs of organic disease fail. An affection which he characterizes artificial membranous colitis is the passage of mucous casts in cases of ordinary colitis when local applications of astringents are made. Boas has convinced himself that the cast-formation is often due to the astringent and is not spontaneous, and he thinks that it may often be the result of simple enemata or of those containing drugs other than astringents. In discussing symptomatology he states that severe obstipation is always present. Colic may be absent in membranous colitis. Status neurosis is not an essential characteristic disease, and is found in the entire absence of cast-formation in other cases of colitis. Disturbance of nutrition is always present and is important, both as a cause and a result of the disease. In the diagnosis it is important to determine whether the disease is primary or secondary to some other bowel trouble, such as appendicitis, carcinoma, etc. If casts are known to be present the condition itself is readily recognized, but if casts are not known to have been passed, all cases of absence in intestinal disease should be subjected to high colon washings, when casts will usually appear if it be membranous colitis. It is always very important not to overlook grave organic disease; membranous colitis is often only a striking symptom of appendicitis, carcinoma, or diseases of the female internal genitalia. Mucous colic should be diagnosed only when all signs of organic disease are absent in the interval between the attacks of colic. [D.L.E.]

3.—The case was that of an old woman who had difficulty in swallowing, and severe emaciation. There was, however, no regurgitation, and an ordinary stomach-tube passed through the esophagus readily. A diagnosis of **cancer** of the pyloric portion of the stomach was then made, but there was no dilation of the stomach and the whole condition was somewhat uncertain. The autopsy showed a medullary carcinoma of the stomach which involved the whole organ and had transformed it into a straight tube which, owing to adhesions, had assumed a vertical position. The vertical position and motor weakness of the stomach explained the obstruction to passage of food. There was also weakness and slight dilation of the lower end of the esophagus. The absence of regurgitation and, upon sounding, of evidence of decided stagnation in the esophagus, together with severe signs of stenosis, were the striking features in this case and in one reported by Rosenheim, and such symptoms should lead to a suspicion of the condition present in the case. If a diagnosis could be made it might be possible to introduce a tube into the bowel through the pylorus and give the patient nourishment in this way. [D.L.E.]

August 23, 1900. [26. Jahrg., No. 34.]

1. Fifth Report From the Malarial Expedition. R. KOCH.
2. The Doubtful Value of Antitussin as a Remedy Against Whooping-cough. PAUL KRAUSE.
3. The Treatment of Aneurysm with Electrolysis by Means of an Inserted Wire. ALBERT BERNHEIM.
4. What Part Do the Tubes Play in the Therapeutic Application of the Röntgen-rays? STRÄTER.
5. Does Alcohol Act as a Food or a Poison? KASSOWITZ.

1.—Koch reports that in Stephansort in the spring months of this year, although the conditions of the weather were extremely favorable for the development of malaria, there were but rare instances of recurrence of malaria. In the month of May but 3 cases were admitted to the hospital; in the first half of June but one case; all were recurrences of quartan fever. This is an exceedingly striking reduction of cases, and he attributes it to the prophylactic use of quinin, instituted according to his suggestion with the idea of preventing recurrence of malaria, and of thus preventing the inoculation of new individuals by means of these old cases. Any general attempt to kill mosquitos he considers will prove impossible. The use of mosquito nets is only a partial aid in the prevention of the disease, and he thinks that only the prophylactic use of quinin will prove sufficient to stamp out

the disease. He intends to continue his investigations on the influence of quinin in other regions. [D.L.E.]

2.—Krause has carried out an investigation on the value of **antitussin in whooping-cough**, giving it to 15 cases and comparing the results with 3 other series of cases, each consisting of 10 children, the one series treated by bromoform, the second by quinin, and in the third no medication was used. The records of the cases during this time showed the number of the daily paroxysms, and included notes of hemorrhage from the nose, vomiting, and other symptoms. There was no evidence that antitussin had any special effect. These cases were not picked cases, hence the test seemed a fair one. Krause also states that since antitussin is a fluorin preparation it is likely to cause unpleasant collateral effects, chiefly on the mucous membranes and skin, since it is somewhat caustic in its effects. Eight of the 17 children treated with it showed obstinate ulceration of the places upon which the antitussin was locally applied. He considers that it should not be used. [D.L.E.]

3.—Bernheim says that **aneurysms** may be sometimes cured by electrolysis when other methods have failed. The method consists in passing a quantity of fine wire through an insulated canula into the aneurysm and connecting this wire with the anodal pole of a galvanic battery. He says that only about a dozen cases have thus far been reported which were treated in this manner, and he therefore gives the history of another case. The patient was a man of 45 who had an aneurysm projecting on the right of his sternum. At the first operation 27 meters of a fine gold wire were introduced into the aneurysm and a current of from 10 to 80 milliamperes kept up for one hour. About 2½ months later a second operation was undertaken. At this time the sac was notably shrunken and the needle had to be introduced to more than twice as far as at the first introduction in order to draw blood. A month later, a number of exploratory punctures were made and only once was the puncture followed by the flowing of blood. Electrolysis was again performed. Four months after this the patient was seen and the aneurysm seemed cured, the patient being able to return to his work as a traveling agent. [G.B.W.]

4.—Sträter calls those tubes whose rays are chiefly absorbed by the skin or muscles, "**soft**." The tubes whose rays chiefly pass through the skin and muscles he calls "**hard**." Besides considering the character of the inductor, the strength of the current, the duration of the exposure, the rapidity of the interruptions, and the distance the tube is removed from the tissue, he thinks that one should consider whether the tubes are "**hard**" or "**soft**" in choosing them for special purposes. If superficial conditions, such as skin affections, are to be treated, he thinks that soft tubes should be used; if deeper situated diseases, the harder tubes should be used. [D.L.E.]

5.—Kassowitz, after reviewing the metabolism work that has been done on the influence of alcohol, decides that alcohol can in no sense be considered a nutriment, apparently chiefly basing his opinion upon the belief that a poison is always a poison, and it does not make any difference whether its good effects are large or small. It is still a poison, and must always be considered a poison. [D.L.E.]

Centralblatt für Gynäkologie.

September 15, 1900. [No. 37.]

1. Remarks Upon the Tübingen Experiments in Disinfection of Hands. F. AHLFELD.
2. A Case of Colossal Fibromyoma of Fundus Uteri. A. PINNA-PINTOR.
3. Upon Contracted and Relaxed Condition of the Uterus in the First Months of Pregnancy. OSCAR BEUTTNER.

1.—Ahlfeld compares the value of 46% solution of spiritus saponis (tincture of green soap) and a 96% solution of alcohol for the disinfection of the hands with a preference for the latter. He thinks the former can not disinfect at all without a previous washing with hot water and soap. The addition of sapo kalinus to the alcohol has no effect worth mentioning, as he had proved by adding 5, 10, and 15% of it to the 96% alcohol. The disinfecting power was exclusively in the alcohol. [W.K.]

2.—Pinna-Pintor reports the successful removal, from a woman of 43, of a fibromyoma weighing 12 kg. and

measuring in its vertical diameter 120 cm. and 100 cm. in the transverse. The case was worthy of notice in that notwithstanding the extraordinary size of the tumor, the uterus had suffered no change in size or consistency, there had been no hemorrhage, and all the pains were caused by the pressure. The recovery was uneventful. [W.K.]

3.—Beuttner gives the history of 2 cases to confirm his theory of the alternate relaxation and contraction of the uterus in the first 2 or 3 months of pregnancy. He claims that after a relaxed or softened condition during the first month, in the second month there is a period when the uterus seems smaller and of firm texture, simulating a nonpregnant uterus, which subsequently again relaxes and enlarges. [W.K.]

1. Sensory Interference. ADAMKIEWICZ.
2. The Sound-Conduction of the Cranial Bones in Diseases of the Brain and its Membranes. WANNER and GUDDEN.
3. The Clinical Position of the so-called Erythrophobia. FRIEDLANDER.

1.—Adamkiewicz insists that we should discriminate sharply between subjective and objective disturbances of sensation; the former are the result of some external stimulant, the latter, of the diseased condition of the brain. The objective disturbances, therefore, are due to some pathologic condition of the conducting apparatus; the subjective, to some disease of the central nervous system; and comprise practically the phenomena known by the term "paresthesia." When paresthesias exist they frequently interfere with the perception of normal objective sensation, because they are probably localized in the spinal cord and interrupt at this point the conduction of irritant stimuli. [J.S.]

2.—The method of Bezold for testing hearing by means of a series of tuning-forks and whistles, giving an almost continuous series of notes, when applied clinically, frequently enables a distinction to be made between organic, or purely functional conditions, such, for example, as cerebral lues, epilepsy, etc., and traumatic neurosis. The series extends from C₂ to the third C of the treble, and the number of vibrations varies from 16 to 50,000. Each ear is tested for whispering speech, for the lowest perceptible note, and for the duration of the perception by bone-conduction. Comparison is then made between air and bone-conduction, the upper perceptible note is determined, and finally an investigation is made in order to show whether by bone-conduction the sound is always heard more distinctly in one ear than the other. If the disease is in the middle ear whisper-speech is diminished, the perception for bone-conduction increased, and the sound is heard more distinctly on the tested side. If in the internal ear, the duration of the perception for bone-conduction is decreased or perhaps completely abolished, the upper note is not so distinctly heard, and there may be imperfections in the scale. In many cases of insanity that the authors examined they were able to determine a considerable reduction of bone-conduction. In a series of normal cases taken for comparison, it was found that the upper perceptible note equaled from 46,000 to 50,000; and that air-conduction persisted longer than bone-conduction; variations in duration of bone conduction of 2 or 3 seconds, however, lay within normal limits. They give the results of the examination of 3 cases, one of cerebral hemiplegia, and 2 of chronic alcoholism; one of the latter also suffered from cerebral tumor. [J.S.]

3.—This article is devoted to the abstracts of 23 cases of erythrophobia, collected from the literature. It is still unfinished. [J.S.]

Practical Therapeutics.

Under the charge of

A. A. STEVENS, A.M., M.D.

Heroin as an Analgesic.—Brown and Tompkins (*Therapeutic Gazette*, August 15, 1900) report 50 cases, in which they employed heroin as an analgesic, or a hypnotic. In 34 cases, it was used for its analgesic effect, and 16 for its hypnotic effect. In all but 7 cases, sleep was induced, and pain was relieved. The action of the drug took place in 15 minutes from the time of administration in 25 cases; in 20 minutes in 18 cases; in the other 7 cases no effect was produced. The dose in 34 cases was $\frac{1}{2}$ grain of the hydrochlorate; in 16 cases $\frac{1}{4}$ grain was given. In 30 cases, the duration of the action of the drug was 4 hours, in 13 cases from 6 to 8 hours, and in 7 cases no appreciable effect was noted. Thirty-one administrations of the drug were given by hypodermic injection, the remaining 19 by the mouth. Vomiting was absent in all but 4 cases, and, as the administrations were made before the patients had fully recovered from the effects of ether, it would be difficult to say which was the cause of the vomiting. Contraction of the pupils and subsequent constipation were absent in all cases. We did not find any idiosyncrasy for the drug, such as has been reported by other observers. The authors conclude that heroin is a safe analgesic, one which can be repeated if necessary without producing habit, or doing harm in any way.

Pastils for Throat Affections.—According to *The Laryngoscope*, the following pastil, when dissolved upon the back of the tongue, 20 minutes before using the voice, is useful in clearing the bone when hoarse or husky:

R.—Benzoic acid.....	$\frac{1}{2}$ grain.
Boric acid.....	1 grain.
Coca.....	$1\frac{1}{2}$ grains.
Black currant paste.....	q. s.

The following pastil, containing guaiac, is highly recommended in acute tonsillitis and acute pharyngitis:

R.—Resin of guaiac.....	2 grains.
Morphin bimeconate.....	$\frac{1}{100}$ grains.
Tincture of aconite.....	2 minims.
Oil of cinnamon.....	$\frac{1}{4}$ minim.
Powdered cinnamon.....	1 grain.
Black currant paste.....	q. s.

Röntgen Rays in Painful Affections.—Stembo (*Therapie der Gegenwart*, June, 1900) reports the results of a series of experiments undertaken to determine the analgesic effect of the Röntgen rays. The rapidity of the interruptions was about 1500 a minute, the duration of the application was from 3 to 10 minutes, and the treatment was applied usually on alternate days. Relief usually follows after three applications; if no results are obtained after ten applications, the treatment should be discontinued. Only the cathodal rays are effective, and since the anodal rays exert little or no influence, the author is of the opinion that the good results cannot be attributed solely to suggestion. Twenty-eight cases are reported, including all the ordinary forms of neuralgia, and of these 21, or 75%, were promptly relieved. When the applications are to be made to the face the author directs that unaffected parts should be protected from the rays by a thin piece of tinfoil.

Dilation of the Heart.—Broadbent (*Heart Disease*, 1900), after alluding to the value of mercurial purgatives and of local or general bloodletting, writes as follows concerning the use of cardiac stimulants: "The heart being relieved of work may be urged to more vigorous contraction by digitalis, strophanthus, spartein, squills, caffeine, convallaria, apocyanum, the special heart tonics, with which strychnin may usually be combined with advantage. In a case of extreme suffering, digitalis may be given with ammonia, ether and nux vomica; in a more chronic stage, with iron, strychnin, and perhaps nitric or hydrochloric acid. Sometimes an effect can be obtained by giving citrate of caffeine in a pill, at the same time with digitalis in a mixture. When singly neither seems to be efficacious. Squills, again, may be given with digitalis, as in the well-known pill with mercury, or in

some liquid combination. Next to digitalis stands strophanthus, which is a most valuable alternative when digitalis seems to produce sickness, as is sometimes the case, or when it fails to exercise a favorable influence on the heart. Sulfate of spartein I have seen to be of great service when digitalis and strophanthus appeared to have exhausted their influence. Of convallaria I have little to say. Apocyanum has in one or two cases seemed to carry off dropsy in a remarkable way, but one patient died suddenly when apparently just well."

Acute Bright's Disease.—J. Mitchell Bruce (*Treatment in Practical Medicine*, 1900) summarizes the treatment of this condition as follows: Rest in bed, in a room at not less than 60° F.; flannel garments, blankets, no sheets; careful nursing. Warm baths; never cold. If lumbar pain, free hematuria and scanty urine; a hot-water bag to loins, or dry cup. *Diet*: Milk only, or milk and water. *Medicine*: A regular morning purgative:

R.—Potassium bitartrate.....	2 drams.
Sodium tartrate.....	10 grains.
Tincture of bitter orange-peel.....	15 minims.
Srup of orange.....	30 minims.
Distilled water to make 1 ounce.	

A saline diuretic and diaphoretic mixture:

R.—Potassium acetate.....	20 grains.
Potassium bicarbonate.....	10 grains.
Solution of ammonium acetate.....	2 drams.
Tincture of lemon.....	10 minims.
Srup.....	30 minims.
Water to make 1 ounce.	

Every 6 hours.

If no complications occur, continue the general treatment and diet, but presently begin to modify them in detail. In the more severe cases: Vapor or hot air baths. If cases do well, allow in addition to milk in different forms farinaceous foods; then, in succession, light vegetables, subacid fruits, fish, fowl or game, fat bacon—watching the urine, the pulse, and general strength. Abundance of distilled water or Vichy, or imperial drink with the solid meals.

R.—Potassium bitartrate.....	5 drams.
Srup.....	a sufficient quantity.
Boiling water.....	1 pint.

To be drunk *ad lib.* No stimulants. Very gradual cautious return to sitting up and movement. *Medicines*: A mild, unstimulating, hematuric and diuretic mixture:

R.—Iron and ammonium citrate.....	5 grains.
Potassium citrate.....	15 grains.
Fluid extract of squill.....	1 minim.
Sweet spirit of niter.....	30 minims.
Srup of orange.....	30 minims.
Distilled water to make 1 ounce.	

Three times a day after meals. A regular morning purgative.

The Treatment of Epilepsy.—Fleury (*Journal de Médecine*, May 10, 1900, and *British Medical Journal*, August 4, 1900), who has made a careful study of the treatment of epilepsy, strongly believes in the autotoxic nature of this neurosis, and therefore considers that diet forms one of the most important elements in the treatment of epilepsy, and should be combined with methods tending to free the gastrointestinal tract from toxic material. Fleury admits that some cases of epileptic seizure seem to be directly due to lesions, meningeal and otherwise, of the central nervous system, and such accordingly are very difficult to treat, but many others, and by far the greatest number, show no cerebral lesion other than possibly some inherent excitability, but in whom disorders of circulation, be they due to auto-intoxication or reflex irritation, are the cause of the seizure. These seizures may vary in very many respects, under the influence of diet, suppression of alcohol, etc. Patients so affected must have their diet carefully regulated and all the surroundings modified, and after this bromids may be administered. These latter become more efficacious when patients have been properly prepared for their exhibition. The writer points out the extreme frequency of gastrointestinal disorders (possibly dilation of the stomach), atony of the intestine, and constipation. Indicanuria is also

a frequent feature. Such patients are put on dry toast, boiled eggs with ham, light fish, such as sole, whiting, veal, chicken, beef, and mutton in small quantities for the first midday meal, and an extremely reduced quantity at night, the last meal being preferably vegetarian. Dry cakes, biscuits, one or two glasses of water, especially mineral or hot water, should constitute the only beverage, alcohol being contraindicated. Eucalyptin, cascara, and similar drugs should be freely administered, while copious enemata should be given daily. Should there be any extreme dilation of the stomach this organ should be washed out. Under such conditions of diet the bromide, especially the bromid of soda, will render much service. Chloral has also been found of much use. The administration of bromide should be relegated to the time of the seizures according as they are nocturnal or diurnal. In the case of daytime fits bromid should be administered before each meal. Massage, cold douching, brine baths, and mountain air are all more or less of great importance. The injection of an artificial serum, consisting of 1% of phosphate of sodium, sulfate of sodium, chlorid of sodium, and carbonic acid, is useful. Eight to 10 grams of this may be administered daily by hypodermic means. According to the writer, some weeks of such treatment should stop any tendency to epileptic seizure.

Orthoform.—Sprague (*The American Therapist*, September, 1900) mentions some conditions in which he has found orthoform useful. In carious teeth with exposed nerve-endings a piece of cotton dipped into a saturated solution of orthoform and alcohol, packed not too tightly, will stop the toothache in 3 or 4 minutes, and will hold its anesthetic effect for several days if packing is not removed. In hemorrhoids it is most valuable in 10% quantities combined with chrysarobin, belladonna, iodoform and lanolin, as an ointment for external, or cocoa butter in place of lanolin as suppositories for internal (rectal) use. In burns of the first degree, 10% orthoform with lanolin containing 5% ichthylol is the best remedy the author has ever used, and in burns of the second and third degree orthoform and boric acid, equal parts, or orthoform alone, is all that is necessary. In all minor operations under cocaine-anesthesia we always have an intense burning in the incisions for from one to four hours afterward, but by dusting orthoform into the stitches we gain complete anesthesia of the part until well. In the dermatitis of rhus poisoning the author has found a combination of orthoform, dermatol and starch highly efficacious.

Cacodylate of Iron.—Gilbert and Lereboullet (*Journal des Praticiens*, September 1, 1900) conclude that cacodylate of iron is very soluble; that it may be readily administered either hypodermically or by the mouth; that its toxicity is very slight, and that it may be employed with advantage in all cases in which it is desirable to increase not only the number of red blood-cells, but also the amount of hemoglobin. It is especially indicated in chlorosis, and in the chloroanemia of tuberculosis. The drug is not irritating to the kidney, and so it may be employed in the anemia of nephritis. In 5 cases of nephritis in which cacodylate of iron was employed, there was, in addition to the general improvement, a marked reduction in the quantity of albumin contained in the urine. The dose to be employed hypodermically is $\frac{1}{2}$ to $\frac{3}{4}$ of a grain daily, by the mouth, 1 to 2 grains or more a day.

Protargol.—Stephenson (*The Therapist*, May 15, 1900) states that he has tried protargol in several kinds of ophthalmia due to gonococci, Koch-Weeks bacilli, diplobacilli, Klebs Löffler bacilli, and in trachoma, acute and chronic. In gonococcal ophthalmia, mainly in newly-born children, he has experimented with solutions ranging in strength from 5 to 50%. The eye was kept clean by the frequent use of a weak antiseptic solution, and the exposed conjunctiva freely brushed once a day with a solution of protargol. For several months he has employed exclusively the 50% solution, twice daily in severe cases. He believes that protargol yields better results in the management of these cases than any of the other silver salts or compounds, including the nitrate. Its application is painless, and, so far as he knows, never gives rise to conjunctival eschara. It may be employed even when the cornea is ulcerated, and, indeed, the existence of such a complication furnishes an additional reason for pushing the remedy. He has not found, what some have claimed, that there is a speedy disappearance of the gonococci from the

secretions under this or any other treatment. The persistence of those organisms, practically as long as there is a trace of discharge, must be a fact familiar to all who have made bacteriologic investigations. In acute contagious ophthalmia (Koch-Weeks bacilli) protargol (20% solution) was not so efficient as a 2% solution of lunar caustic or a 10% solution of largin. In diplobacillary ophthalmia protargol in the author's hands gave no satisfactory results. In conjunctival diphtheria, protargol was used in conjunction with antitoxin with apparent success. No tangible results were obtained in chronic trachoma. In acute trachoma infinitely better results were obtained with both silver nitrate and largin. Protargol is an excellent remedy for use in catarrhal inflammations of the nasal sac—of course, after slitting up the canaliculus and probing the nasal duct.

Petrosulfol.—Ehrmann (*Wiener klinische Rundschau*, No. 18, 1900) states that petrosulfol is a sulphur compound similar to ichthylol in its physical and chemical properties. While he found the drug valuable as a local application in dry eczemas, the best results were obtained in eczemas associated with scales (eczema keratoides); excellent results were also obtained in cases of sycosis and pustular eczema. The remedy was employed in the form of an ointment, or in a paste like the following:

R.—Petrosulfol 6 parts.
Lanolin 20 parts.
Vaselin 20 parts.
Zinc oxid, starch, or talc..... 10 parts.

Occasionally it may be necessary to make the paste not quite so stiff, in such a case only half of the zinc oxid or starch may be used. In sweaty hands and feet the author found 5% solutions of petrosulfol alone, or in combination with salicylic acid very efficient. As a dusting powder in erythema the author recommends:

R.—Petrosulfol 5 parts.
Venetian talc..... 50 parts.
Starch 100 parts.

or,

R.—Petrosulfol 6 parts.
Venetian talc..... 60 parts.
Magnesium carbonate 40 parts.

The Treatment of Facial Paralysis.—Short (*Birmingham Medical Review*, April, 1900) states that a blister behind the ear often renders great service in the early stage of the affection. When blisters are inadvisable, stimulating liniments may be rubbed in over the mastoid process. As in other forms of neuritis potassium iodid (5 grains thrice daily) is usually prescribed, but the author believes that it is generally unnecessary. At the end of two weeks strychnin is given and continued until the muscular contraction is almost as good on the affected side as on the sound side, and is then stopped. Galvanism, however, is the most valuable treatment, and this should be employed early. According to the author, the third day of the paralysis is not too soon, and the weakest current that will cause contraction of the muscles should be used. Prognosis based upon the presence or absence of the reactions of degeneration is not always to be depended upon, for in one case they were well marked on the fifth day, and the patient was quite well within a month. Faradism is not absolutely necessary, and when the nerves respond less readily to it than galvanism it should be avoided. Later, however, when reaction to faradism is normal, but voluntary action of the muscles is weak, a combination of the two currents will often hasten recovery. In chronic forms, especially when little voluntary power has returned, the author recommends the use of a "face crutch." This consists of a small silver hook placed in the corner of the mouth, and attached by means of an elastic loop to the ear of the same side. Every movement of the muscles of the lips and cheeks alters the tension of the elastic pull on the hook. The pull is in direct antagonism to the action of the orbicularis, so that the work of that muscle is increased. The tension of the elastic should be such that the pull on the corner of the mouth is sufficient to widen the aperture about one-quarter of an inch. The apparatus should not be worn more than 10 minutes at first, and never for more than an hour at a time. If a feeling of cramp in the cheek develops the hook should be removed and the muscles rested. In addition to this artificial exercise of the muscles massage should be employed.

Original Articles.

THE ETIOLOGY OF YELLOW FEVER.

By EUGENE WASDIN, M.D.,

Surgeon M. H. S., Buffalo, N. Y.

SINCE the publication of the memoirs of Giuseppe Sanarelli in June, 1897, upon his studies in yellow fever, the medical profession has been intensely interested in the subject. As it is now well known, Sanarelli based his claim to the discovery of the cause of the disease upon inadequate experimental evidence, his *Bacillus icteroides* having been shown to possess only pathogenic powers when artificially inoculated into animals. However, prior to these memoirs of Sanarelli there is nothing written which throws the slightest light upon either the cause of the disease, or its natural and clinical phenomena. The report of the Commission of Medical Officers of the Marine-Hospital Service upon this subject, made in July, 1899, sustained the claim of Sanarelli, and in addition offered evidence in proof of the specificity of *Bacillus icteroides*, and an explanation of the natural and clinical phenomena of the disease. Since that report has been published there have appeared a number of contributions upon this subject in the medical, and unfortunately in the lay, press, many of which have been condemnatory of the claim of Sanarelli of having discovered the germ, and of the work of that Commission in sustaining him, and in the elucidation of the disease. Of these the one contributed by Dr. Charles Smart, U. S. A., to THE PHILADELPHIA MEDICAL JOURNAL of the 20th, and that read by Drs. Reed, Carroll, and Lazear at the recent meeting of the American Public Health Association, and published in the same journal of October 27, will alone receive attention.

In his article Dr. Smart introduces in condemnation of the claim made by us for *Bacillus icteroides*, the fact that Agramonte had isolated this bacillus from the bodies of three persons dead of some disease other than yellow fever. I will only ask attention, in reference to these cases, to an article, which utterly refutes them, by my laboratory associate, Dr. Francesco E. Menocal, U. S. M. H. S., published in Toma 10, Entrego, of the *Archivos de la Sociedad de Estudios Clinicos de la Habana*. Dr. Smart also introduces entire a letter written by Lutz, of San Paulo, Brazil, in which *Bacillus icteroides* is condemned because of the results obtained from the antiserum prepared from it. Lutz recognizes *Bacillus icteroides*, since he has isolated it from 50% of his cases, but denounces it because its antiserum is found to be neither antitoxic nor germicidal *in vitro*; hence he contends that it is *inert*.

Sanarelli and ourselves recognize fully these facts, but we cannot accept the contention. The same facts are recognized in regard to the famous Roux serum antipesteuse. It is *not* antitoxic, nor is it germicidal *in vitro*. Yet it is equally well known that the serum antipesteuse, when introduced into the circulation of animals, in which *Bacillus pestis* is present with impunity among the phagocytes, induces such changes in the cells of *Bacillus pestis*, that the phagocytes can now engulf them and bear them away. This force not present in the blood *before* the injection of the serum is *at once* observed *after* its use. The pest organism is not *killed* by this influence—far from it—but it is *inhibited*, and the leukocytes can then act upon it.

This fact is evident from the experience of Calmette

and Salembini, who found that in certain cases of peste, which they term "secondary infection" of the lungs, a theory which I have shown to be erroneous, the patients die in spite of the copious use of the serum antipesteuse, because its *inhibitive influence, exercised so clearly upon Bacillus pestis in the blood-current, is not so powerful when brought to bear upon the concentrated primary colony of the germ in the tissues of the lung*. In other words *protection after infection* does not depend upon the *immediate death* of the invading organism, but upon the exercise of the *inhibitive power* of the serum, after which the phagocytes do the rest. The deleterious influence of any organism depends upon the development of its inherent qualities by its environment. In natural immunity the quality of specificity is not developed because of the environment, nor is there necessity to speak of the combination of certain chemical agents with the toxins from these germs to account for natural immunity, which depends upon an inherent potential of the bacterial cell, and unless this is developed there can be no infection, and therefore no need for protection. After such development specific disease results, and a specific antitoxin, or a specific *antiseptin* is developed according to the type of the disease. It is this latter body, produced in the blood of the horse after inoculation with *Bacillus pestis*, which *inhibits* the germ after natural infection of man, phagocytosis accomplishing their *further destruction*. If there could be produced also an antitoxin from this bacillus the cure of practically all cases of pest would be assured. The antiserum of yellow fever possesses the same quality of power as that of pest, and we have no doubt of finally producing an antiserum of value, although this may depend upon the environment of the animals in which it is produced. The letter of Lutz is directly in favor of the claims for *Bacillus icteroides*.

As to the paper presented to the American Public Health Association by Reed and Carroll, there is not much to be said in reply. In regard to the first portion of it, treating of *Bacillus icteroides*, it is scarcely necessary to call attention to the fact that the absolute failure of these observers to isolate *Bacillus icteroides* from the living blood, employing as they confess a method of collecting it entirely different from that employed by us and by other observers, and discountenanced by many authors, simply proves the inutility of the method employed by them, and does not bear directly upon the question of the presence of *Bacillus icteroides* in the blood of yellow-fever patients. Their failure to find *Bacillus icteroides* in the autopsy cases causes the *surprise of even one of their own colleagues* and, in view of the facts established by others, must depend upon a want of proper conception of the difficulties encountered and the labor demanded in isolating this organism.

They remark in this connection that the colonies of other organisms in gelatin closely resemble those of *icteroides*, and generously comment: "We wonder whether other observers have occasionally relied upon the appearance of colonies in gelatin plates, *without further study*." (The italics are mine.) This is ingenious, since in *our* report of our work we have explicitly stated that no organism was accepted as *Bacillus icteroides* until it had been made to fulfil every demand that could be made upon it, and that all these cultures had been preserved and presented in evidence to our Surgeon-General upon our return to the United States. It is neither scientific nor generous to endeavor to

impugn the motives or results of coworkers, however much we may differ from them in the construction to be placed upon those results. The attitude of the authors towards Sanarelli and ourselves is as unfortunate as it is well known.

Because of their failure, through the employment of strictly venous blood in sowing, to isolate *Bacillus icteroides* from those ill with yellow fever, these observers condemn ourselves with 92.8%; P. E. Archinard with 85%; Potier with 82.6%; Sanarelli with 55%; Lutz of San Paulo, Brazil, with 50%, and lastly their colleague, Agramonte, when employing the same technic, with 33.3% of isolations of *Bacillus icteroides* from those ill with yellow fever. Can any one accept their dictum under these circumstances? I think not, for their failure does not affect the question of the etiology of yellow fever.

In this connection they remark that Veasie (New Orleans) states that Potier *did not isolate* *Bacillus icteroides* from any cases during the fever of 1899. That is incorrect, since Veasie allows Portier to state himself as follows: "From all autopsies held of suspicious cases cultures were made and they remained free from *Bacillus icteroides* . . . In the blood of these cases *Plasmodium malariae* was found before death . . . and in the blood taken at autopsy." Reed and Carroll failed to state that Veasie's paper treated of *estivo-autumnal* fever and not of yellow fever; and to the contrary of their statement is the fact that Potier continues: "As to the cultures obtained from living blood during the prevalence of the fever in 1898 (yellow fever in New Orleans) I obtained pure cultures of *Bacillus icteroides* in 19 cases out of 23. The method I used was to puncture the lobule of the ear, after thorough cleaning of the parts, with a sterile lancet, and allow from 15 to 20 drops of blood to flow into a small tube containing sterile bouillon and plating . . . The same methods were used in 1899 (*estivo-autumnal* fever) and no *Bacillus icteroides* was found."

These italics are mine, since it is necessary to clear up this matter so imperfectly remembered by Reed and Carroll, and since it shows so clearly the superiority of using capillary blood in planting over that of using .5 cc. of venous blood, as practised by these observers. Their technic is proved to have been faulty, this fault representing with us the difference between 92.8% and 0%.

As an offset to this failure they introduce some observations made at the suggestion of Dr. Carlos Finlay, of Havana, upon the influence of the mosquito (*Culex fasciatus*) in the propagation of the disease. While in Havana we were shown by Dr. Finlay, with that rare courtesy and scientific interest which characterize him, his painstaking and continuous (over several years) work in this direction; and during our conversations I assured Dr. Finlay of my deep interest in the plausible theory, so far as the carriage of the disease was concerned, since I could not deny the possibility of any acute septic organism being introduced into the blood by this artificial means and causing its specific disease; my principal reason for not accepting his theory of such *artificial inoculation* being the fact that I had never known a case of yellow fever thus contracted, although *my own severe case* was contracted a few days after I had incised my hand while making section of a yellow-fever cadaver in 1897.

Dr. Finlay's percent of cases resulting in fever after these artificial attempts at infection is only that which

would naturally be expected among a number of well-to-do persons (mostly Spanish clericals) coming to Havana during the winter months in order to escape the severity of the disease; and it is a well-known fact among the Cuban physicians that these acclimatizing (ephemeral) attacks freely occur in Havana. And it will be recalled that at that time, prior to the studies of peste at Oporto, Portugal, and our own conclusions in yellow fever, it was almost generally conceded that the peste was an artificial inoculation through the bites of certain insects, an error from which we are now fortunately freed, although the menace from the bites of these insects forcibly reminds us of the saying concerning the noisy dog. Therefore I am open to the concession that *Culex fasciatus* may be a possible (not probable) agent in the carriage of *Bacillus icteroides*, just as the fly does *Bacillus typhi abdominalis*, or the flea carries *Bacillus pestis*. Only this and nothing more.

With presumably infected mosquitos these observers inoculated 11 reagents, and two of these reacted in a given time to the supposed virus. Let us analyze these two cases in all scientific fairness. That of Dr. Carroll, one of the inoculées, was contracted within five days of a visit to one of the dirty autopsy rooms at the Military Hospital in Havana, wherein an autopsy upon a yellow-fever cadaver had been held only the preceding day; he had, besides, the habit of entering the yellow-fever wards of other hospitals for the purpose of studying the disease. Therefore this case, so fairly open to just criticism as to the possible mode of infection, should be discarded. The second case to react, that of a soldier "X. Y.," occurred in a barrack in which there has been yellow-fever during the summer, and situate only six miles from Havana. This soldier was in the laboratory in which the work was being conducted, and in which Dr. Carroll worked, on the day when Dr. Carroll, sick for three days, was compelled to seek his bed, or the 31st of August, the day on which the inoculation of the soldier took place. Since we have only the statement, dependent upon his freedom from discomfort, of this man that he had not visited Havana during the preceding days, the fact of his nonexposure in that city remains in doubt, and the case is open to question.

The case of the highly gifted and universally esteemed and regretted Lazear is even more open to criticism in this relation than the others. In other words, nothing has been proved, neither that there is *anything new* in the blood of yellow-fever patients, nor that these cases were not the result of natural infection, nor yet, and it is of some importance, that there is anything of interest in the middle intestine of these supposedly infected mosquitos. Pure speculation cannot be accepted.

Sternberg in a recent note said, "From Wasdin's point of view the question of yellow-fever etiology is settled." Nothing is more certain than that fact, and I will here repeat my reasons for occupying that position for fear that it may sound egotistic.

Laborious clinical observation carried on through many years has culminated, in the past two decades, in the formulation of a group of diseases called, by international consent, the "acute infectious diseases."

All of them have characteristics in common; primarily, they are infectious; then, they are characterized by clinical symptoms due to the influence of intoxicants, each one of them exhibiting, however, some special reaction or symptom which serves to identify the disease; that is to say, they are all specific infections;

and, finally, we now know that many of them are caused by vegetable microorganisms of low type.

Clinically these diseases resemble each other closely until the development of their specific symptoms, after which they are readily diagnosticated.

Pathologically it is known that the chief disasters arise from the influence exercised by the toxins, formed by these organisms, upon the highly organized cells of the parenchyma of the organs of the body attacked, such as the fatty degeneration of the cells of the liver, kidneys and other organs, and the necrosis found at times in the same tissues.

In some of these diseases the toxins absorbed from the primary and localized colony alone cause these changes; while in others the infecting organisms are found to have passed from the primary colony into the circulation, and thus add to the effect of the toxins absorbed from the primary colony, the type of which we have in enteric or typhoid fever.

So much for the disease. The causes of these infections are important, and in the study of them the causes and effects must be approximated, and should be in harmony.

Each one of these infecting organisms is specific, and it is only so when it has entered into contact with the living tissues, when, if the environment is propitious, this potential becomes a developed force.

Coinstantaneously there are developed two other inherent forces, or qualities in the infecting germ. These are the well-known quality of toxicity, and the equally important one of septicity, not generally recognized. Upon the development of these latter qualities the type of the attack of the disease about to be produced must depend. Those germs, intensely toxic, produce a reaction characterized by special toxic clinical and pathologic symptoms, among the latter appearing the *fatty degenerations*, and at times the necroses in the parenchyma of the organs.

Those intensely septic are characterized by more prolonged clinical symptoms, *less marked fatty changes and more marked necroses* in the tissues.

These terms toxicity and septicity are therefore *apposites* of each other in their relation to the bacterial cell, and are only potential until developed by the cell environment. These are the three qualities that each specific infectious organism must possess potentially, which make it pathogenic of necessity, although all pathogens are not specific, and are only potentially toxic or septic until introduced artificially into the tissues.

Since, as said above, these inherent potentials when developed must influence the types of cases produced in any of these diseases, it stands that there must be a common law which governs this production, since nothing occurs by chance in nature, and this is the law, that if the toxic potential is strongly developed there will arise the acutely toxic, siderante cases; that if it is only slightly developed such cases will be ephemeral; and if the septic potential is developed, either alone or in conjunction with the toxic, that there must arise the septic cases of these diseases. When these developments are mixed the pathologic changes are found to be combined. The general rule for these pathologic changes applies to all of these infections. There is no exception, and the reason of this probably is that the sepsis tends to a depreciation of the blood towards *anemia*, and it has been observed that anemia, or diseases tending to produce it, tends to *prevent fatty degeneration*, even in the case of phosphorus poisoning.

The three types of cases named are and have been recognized thus far only in yellow fever (Sternberg), although we may now recognize all of them in the other acute infections. It was from my observations in this disease, and from those of Calmette in pest, that I have been enabled to formulate this law, nor does it do any violence to our accumulating knowledge of these affections. It is, therefore, in the application of this law to the acute infection of yellow fever, explaining its symptomatology, and its pathology upon these firm facts, that I now contend that yellow fever can not be rudely torn from its place in the list of the acute infections, and placed, as would Reed and Carroll, in that of the accidental, artificial inoculations, which appears to be the fate of the malarial fevers at this time.

Each one of the specific infectious organisms may be able, under artificial inoculation, to produce its specific disease, as in diphtheria and pest, but that does not remove these diseases from the list of the natural infections. So with yellow fever, its accidental, artificial inoculation by the contaminated proboscis of the mosquito is only of the significance of the pest virus introduced into the blood-current by the flea or other insect.

Therefore, from these facts I must discourage the idea, which the paper of Drs. Reed and Carroll tends to encourage, that the nosology of yellow fever is to be changed, even though their very imperfect observations were more convincing, by the theory of its convection by the mosquito, and will leave the matter of isolating the *Bacillus icteroides* from the blood of those ill with this disease to their further work under improved technic, since I can not accept either of the contentions of their paper under circumstances so open to just criticism.

CARCINOMA OF THE RECTUM.

By JOHN B. DEEVER, M.D.,

of Philadelphia.

THAT important avenue, the rectum, is unfortunately one of the most common sites of malignant disease, and this is especially the case in males. As regards its etiology we know no more than we do of that of carcinoma in general. Systematic writers seem agreed that carcinoma of the rectum, like carcinoma of other portions of the gastrointestinal tract, is more likely to occur in advanced life, that is, after the fortieth year, but this is not in accordance with my experience. It seems to me that age is of relatively little importance as an etiologic factor, as I have encountered the condition as frequently in the young adult as in the aged. Heredity also is of little significance, as in no instance have I been able to elicit a history of the occurrence of carcinoma in the family connections of my patients. As regards the theories that have been propounded to explain the origin of the affection, it may be stated that none is in any way satisfactory.

An idea of the relative frequency of carcinoma of the rectum may be gleaned from the statistics recently collected by Dr. A. O. J. Kelly, and published in his article on tumors of the vermiform appendix which was read at a meeting of the Pathological Society of Philadelphia, March 8, and which appears in the second edition of my "Treatise on Appendicitis." From this communication it is learned that Maydl and

Nothnagel have collected the statistics of the Pathological Institute of the Vienna General Hospital for the 24 years from 1870 to 1893, during which time 41,838 necropsies were performed. Among these were 3,585 cases of carcinoma in general, of which 343 affected the intestinal tract, its various portions being involved as follows: Duodenum 7, jejunum 0, ileum 10, vermiform appendix 2, cecum 23, colon 99, sigmoid flexure 53, and rectum 162. To these Dr. Kelley has added the statistics of Leichtenstern, Bryant, Müller, and Ewald, from which we ascertain that of 1,391 cases of carcinoma of the intestine, the rectum was the seat of the new growth in 988 cases, the large intestine in 251, the cecum and appendix in 79, the ileum in 32, the jejunum in 17, and the duodenum in 24.

Of the malignant tumors encountered in the rectum, several varieties may be distinguished. Carcinoma is by far the more common; sarcoma, however, may occur. It is nevertheless relatively so rare that it possesses but little practical importance. It is generally of the spindle-cell variety, but may be melanotic. If the latter, there may be detected a blackish, soft, generally large tumor, surrounding the rectum and protruding from the anus. The discharge is extremely foul, and the stools are often blackish from admixture of degenerated neoplastic masses. The tumor grows rapidly and quickly infects the general system. The disease is so rare that personally I have never encountered a case.

Of the carcinomas of the rectum several varieties also may be distinguished. Broadly speaking, there are two distinct classes, the squamous epithelioma and the cylindrical epithelioma. These differ not only in situation, but also in general characteristics. The former, the squamous epithelioma, begins at the mucocutaneous juncture of the anus, as a small, hard, dry nodule. It tends progressively to increase in size, though it is generally of slow, and often of very slow growth. It gradually infiltrates the surrounding tissues, and may spread to the neighboring lymphatic glands. Ulceration, if it occurs, does not develop until late. This is the variety of carcinoma that arises at any of the mucocutaneous junctures, especially at the mouth. It is rare, however, about the anus and rectum. Under the microscope it reveals the ordinary characteristics of squamous epithelioma in general. In particular, the well-known pearly bodies are especially conspicuous, whereas in the other carcinomas of the rectum they are entirely absent.

The vast majority of carcinomas of the rectum are of the cylindrical-cell variety. It is likely that some of these carcinomas arise from the surface epithelial cells of the rectum, but most of them develop from the epithelial lining of the glands. In the atypic proliferation that characterizes the carcinoma, the origin of the new growth from these glands is usually very manifest, and it is for this reason that these tumors are most appropriately designated adenocarcinomas. For practical purposes it suffices, therefore, to regard these tumors as adenocarcinomas. Clinically several varieties may be distinguished, and histologic investigation reveals that the clinical classification is well founded. Thus of the cylindrical-cell adenocarcinoma of the rectum we may distinguish the scirrhus, the medullary or encephaloid, and the colloid varieties. Again, there is sometimes encountered a carcinoma of the rectum which does not altogether exhibit the characteristics of the scirrhus variety nor yet those of the medullary form, and which,

being as it were midway between the two, is spoken of as a simple adenocarcinoma of the rectum. This fact merely emphasizes the fact which must be evident to all who have investigated these tumors, that there is no sharp line of demarcation between the different varieties. At one time a carcinoma of the rectum may partake of the peculiarities of the scirrhus variety and at another of those of the medullary variety, though the reverse of this is not likely to be the case. Exceptionally we must admit that it may occur through the degeneration, necrosis, and ulceration of the carcinomatous mass. The larger part of the mass may be cast off and discharged with the feces, whereas the remaining connective tissue, by its cicatrization, tends to the production of the characteristics of the scirrhus variety. In other cases, in one portion of the growth, the appearances may be those of the typical scirrhus, while in another they may be those of the medullary form. In other cases the so-called colloid degeneration is more or less marked, while in a few instances this assumes the predominance. There occur, nevertheless, typical instances of scirrhus, medullary, and colloid carcinoma of the rectum.

Ordinarily adenocarcinoma of the rectum in its early stages presents itself as a more or less circumscribed, roundish or oval nodule that projects somewhat into the lumen of the bowel. At this time it may be quite smooth and movable with the mucous membrane from which it has taken its origin. Its subsequent appearance depends considerable upon its histological structure, but also upon other factors with which we are poorly acquainted. Generally it tends to more or less rapidly infiltrate the submucous tissues—the submucosa, the muscularis, and the perirectal connective tissue. It may remain somewhat circumscribed to one side of the rectum, or it may encircle the bowel and lead to considerable constriction of its lumen. It tends to ulceration, and when this occurs the examining finger encounters a mass of soft and necrotic neoplastic debris, around which there may be detected the harder and raised edges of the indurated ulcer. This induration may also be found to extend to the surrounding tissues. In the neighborhood of the large ulcer several smaller nodules or ulcers may be detected. As a consequence of ulceration and necrosis these tumors are likely to give rise to considerable hemorrhage.

Under some circumstances the malignant growth is encountered as an encapsulated lobulated mass which grows rapidly and may reach an immense size. The mass may be firm or semifluid, and vary in color from grayish-white to a reddish color, the latter the result of the admixture of more or less blood. Later the seeming capsule of the growth may burst and the contents will be extruded and present the appearance somewhat of brain-tissue. This is the variety of carcinoma of the rectum spoken of as encephaloid. The fluid expressed from the tumor colors water a milky-white, a sign which Paget considered pathognomonic of this form of carcinoma. This tumor grows with great rapidity, and is very malignant in that it gives extensive metastases to the general system and recurs soon after removal.

Somewhat more common than the encephaloid variety is the scirrhus carcinoma of the rectum. Clinically it appears to begin in the submucosa, and is usually first detected on the anterior surface of the rectum in the neighborhood of the prostate gland. It presents the characteristics of a hard, fibrous mass, which often is not discovered until it has encircled the rectum and caused considerable constriction of its lumen. It tends

to spread upward rather than downward. It invades the surrounding tissues and late in its course may ulcerate. When this occurs, it is usually difficult to distinguish it clinically from the other varieties, particularly as the latter often present analogous appearances in their later stages.

Colloid carcinoma of the rectum much resembles the encephaloid variety. It differs from it, however, in that the large semifluid mass is more jelly-like in character, glistening, translucent, and pale-yellowish in color. These tumors are not uncommon, and differ greatly in malignancy. They do not grow as rapidly as do some others and are less likely to give metastasis so soon; in consequence they frequently do not recur after removal.

As already remarked, a few of these carcinomas may develop from the surface epithelium lining the lumen of the rectum. The vast majority, however, develop from the epithelium of the glands of the organ. Even those which grow in the submucosa beneath a seeming intact mucous membrane can have no origin other than the glands of Lieberkühn. They result from an irregular proliferation of the epithelial cells of these glands, which, as a consequence of their increase in number and their general tendencies, penetrate the muscularis mucosa, and, having reached the submucosa, find a congenial soil for their unhindered growth. Depending upon the relative amounts of the connective-tissue stroma, and the nests of epithelial cells, the tumors partake of the scirrhous or medullary variety. In the former the nests of epithelial cells are small and the stroma abundant and fibrous; in the latter the nest of cells are very large and the stroma very meager. In the so-called colloid carcinoma there occurs an extensive mucoid degeneration of the epithelial cells. Clinically there is often but little difference in the various forms of rectal carcinomas and at times we are able to distinguish but the squamous and cylindrical varieties—the latter, as has already been stated elsewhere, being spoken of as adenocarcinoma. We must also bear in mind that some of the benign polyps and so-called villous tumors of the rectum are prone to malignant transformation and that a carcinoma may thus arise. The indications for treatment, however, in all cases is the same—operation.

The symptoms of carcinoma of the rectum, especially in the early stages, bear no relationship to the gravity of the affection. A patient may have advanced rectal carcinoma and suffer but little pain and some diarrhea and rectal tenesmus. However, pain is the most frequent symptom and is usually described by the patients as being extremely severe. In the latter stages it may be continuous, but subject to acute exacerbations during the movement of the bowels, as a consequence of the passage of feces over the ulcerated surface. The pain is most severe when the growth involves the internal sphincter. The pain is caused by pressure or stretching of the nerves supplying the rectum. Tenesmus is often found associated with pain and is a most distressing symptom. Diarrhea is a constant and troublesome symptom. A diarrhea which persists for any length of time, even if there are intervals of quiet, calls for a digital exploration of the rectum. Later stages present symptoms commensurate with obstruction to the passage of feces and systemic infection.

Prognosis depends upon the position and extent of the growth and the time which has elapsed from its incipency.

Ordinarily cancer of the rectum is located about 2½ to 3 inches from the anus. It may start high up or near the sigmoid junction with the rectum. There seems to be something favorable to the rapid growth of high rectal cancer, for certain it is that it is most rapidly fatal and causes early obstruction. Often a colotomy becomes necessary very early to relieve the obstruction and pain.

The characteristic "feel" and odor of cancer renders the diagnosis unmistakable. The only condition for which it can be mistaken is simple indurated ulceration causing stricture of the rectum. The odor and "feel" once recognized will never be forgotten and will make the diagnosis of cancer quite positive.

Unfortunately the disease starts so insidiously that it offers no symptoms proportionate to its severity. I would, however, suggest the advisability of rectal examination in every case of more or less continuous diarrhea, for thus we will discover early cancer and can therefore institute the only means which offer a possibility of a cure.

The treatment consists of radical measures and palliative treatment. It must be suggested that even the most radical measure possible, namely, total extirpation of the growth, is not always successful in securing a cure. However, it alone offers the best chance and is particularly efficacious when undertaken in the very early stages of the disease.

Kraske's operation as I have modified it best meets the indications. I always aim to remove the rectum wide of the disease and to do an end-to-end anastomosis. If an end-to-end anastomosis is impracticable I make an artificial anus in the left iliac region.

Operations through the rectum, such as curetments, applications of cauteries, etc., are only to be classed as palliative measures and are only applicable in the hopelessly advanced cases when extirpation is impossible.

My practice in dealing with carcinoma of the rectum is as follows: Where the growth involves the terminal part of the rectum and includes the anus, the operation of removal is made through the perineum; the mucous membrane of the bowel above being stitched to the skin margin of the circular perineal incision. Where the growth involves the lower portion of the rectum, exclusive of the anus, it is removed through a posterior median incision, taking away the coccyx with, in many cases, the last one or two segments of the sacrum. By this method (modified Kraske), as in that for the removal of a growth occupying a higher location, the diseased portion of the bowel is excised and end-to-end union of the divided bowel made. This permits of re-establishment of the function of the bowel. Where the growth occupies the upper portion of the rectum, and to some extent the terminal portion of the sigmoid, it is removed through the posterior median incision, taking away the coccyx and the lower three or four segments of the sacrum. Here, end-to-end union of the divided bowel is practised. Reference to cases I have reported in the Transactions of the Academy of Surgery, of Philadelphia, for the year 1900, will show three successful cases with complete restoration of bowel function. The section of the sacrum is made with chisel or osteotome, and the ligaments and soft tissues cut with scissors curved on the flat and made to hug the bone, thus dividing the vessels where they are smallest and readily reached. The amount of bleeding is not great, hence the shock is of minor importance. Upon one

occasion I first opened the abdominal cavity and tied the inferior mesenteric artery. This I have never repeated, as I consider it too much surgery where less suffices.

The question of shock is influenced too by the condition of the patient; if much debilitated there will be some shock. I have had to resort to intravenous saline infusion. It will be noticed that the cases of magnitude I have reported, and which include all I have done up to date, have all resulted in recovery. When the growth occupies a high location it is necessary to open the peritoneum, not only to be sure that the bowel has been divided well to the proximal side of the disease, but to give opportunity to draw down enough bowel to render suturing easy and prevent traction or tension. With the peritoneum opened, by the proper disposition of sterile gauze until the excision is accomplished, when the divided parietal peritoneum is stitched to the serous covering of upper portion of the rectum or the sigmoid, as the case may be, infection of the peritoneal cavity is avoided. I have never seen peritonitis follow this operation. After the divided parietal peritoneum is united to the peritoneal covering of the proximal bowel by a continuous Lembert suture the packing is again introduced to further prevent the possibility of peritoneal infection.

It will be noticed that I have said nothing about a preliminary colotomy, my only reason for not mentioning it being that I consider it unnecessary. The latter operation, if done at all, except in the inoperable cases, by which I mean where excision of the growth is inadvisable, I do as a sequel; that is, in the cases where the growth involves the anus and I am not able to save the sphincter muscle and where the patient is not satisfied to have an anus over which he has no control and from the situation cannot comfortably wear a mechanical appliance that will occlude the opening as can be done in the iliac colotomy anus.

The latter operation is only practised when excision of the rectum is to be done later. To divide the sigmoid flexure and close the distal end by invagination where the rectum is not to be excised is a dangerous procedure in that the discharge may collect to the proximal side of the growth to the extent of distending the cut-off segment of bowel to the degree of causing ulceration and perforative peritonitis.

In concluding my remarks upon the subject of carcinoma of the rectum, I regret that more radical surgery than that advised is not permissible; by which I mean, the removal of the lymphatic glands, of the mesosigmoid, in this wise absolutely cutting off the lymphatic circulation between the site of the disease and the general lymphatic circulation. If this was possible, the outcome of these operations would be more promising. In the absence of being able to do this, early and radical operation is all the more urgently called for.

When the growth occupies the rectum high up and I am not able to determine by examination through this avenue or the vagina, I open the abdomen in the left iliac region. If it is now determined that the growth with the rectum can be taken out through a posterior incision the sigmoid is divided transversely and removed with its mesentery as far down as the growth, when the lower opening is closed and the margins of upper opening stitched to the margins of the upper part of the incision, closing the lower part of the incision entirely.

ACUTE HEMORRHAGIC ENCEPHALITIS.¹

A Case of Multiple Terminal-Twig Hemorrhage of the Cortical System of the Right Side of the Brain. Followed by Transient Left Hemiplegia, Petit Mal, and Later Generalized Convulsions. Operation. Recovery.

By CHARLES DEWEY CENTER, M.D.,

of Quincy, Ill.

On February 14, 1899, I was called to the plant of the Quincy Valve Works to see a foreman, W—A—, German, aged 36 years. I found him sitting up, supported by a workman. He showed some tendency to cyanosis. Was breathing, not stertorously, but with some effort. The pupils were contracted, and the temperature subnormal. The pulse was full, irregular, and about 90. His left hand was numb, with diminished muscular force. The left leg was about equally disabled. He had great difficulty in speaking.

The immediate history of the case, elicited from fellow workmen, was that he fell unconscious and in a fit while working. From his family, and from him later, the following remote history was obtained: For two weeks previous to this attack he had been suffering from what they considered grip, and, although he had not quit work, his discomfort, especially the pain in his head, had been so great that he had been unable to sleep for the two nights preceding the present attack. This pain was on the right side of the head, and, in his words, was a feeling of too great pressure. Its seat he designated as behind and above the right eye, extending back over a region equivalent to the upper and anterior parts of the Rolandic area. He denied absolutely any possibility of syphilis, but confessed to using considerable alcohol. He is about 6 feet tall, of full habit, and weighs between 200 and 220 pounds.

On February 13, after a sleepless night, he went to work and found the water pipes frozen. While thawing them out he was compelled, as he worked, to lie in water and ice upon one side. He became very cold, wet, and tired while doing this. That night again he could not sleep, because of pain in head, back, and legs, and went to work the next morning intending to consult a doctor during the day. At 10 A.M., as before stated, he fell unconscious.

After being taken home, the day passed uneventfully, and a few hours in bed with head high and hot bottles at the feet, so restored him that he wanted to get up. The hemiplegia was diminishing, and he spoke with greater distinctness. He was not allowed to leave the bed. Toward evening he began to have periodic attacks of twitching of the muscles at the left angle of the mouth. Immediately preceding these attacks there was a premonitory feeling of numbness of the thumb and forefinger of the left hand. He did not, during the spasms, lose consciousness, and several times was able to count through one, but very indistinctly, as the tongue partook in the spasm, being partially protruded and pushed to the right. As the spasm grew in intensity he would invariably, unless restrained, raise his left hand, gaze steadily and with an extremely sorrowful expression at it, and hold it up until the spasm passed. He could not tell why he did this, nor remember doing it. These spasms lasted about two minutes. During the muscular twitchings his face reddened, the vessels of the conjunctiva and sclerotics became engorged, and the lips a little cyanotic. The pupils would not respond to light, but sometimes he would wink at the approach of a flame to his eyes. He felt no pain other than the headache.

The night of the 14th he slept fairly well, having but 6 or 7 of the facial spasms. He had been placed on full doses of bromid, together with the acetate and citrate of potassium, and broken doses of calomel, as he was constipated and was passing but little urine, and that heavily loaded with albumin.

During the 15th the only change was in the number of spasms and the lengthened duration of each. One or two of them involved both sides of the face. A copious evacuation of the bowels had been secured, and he was excreting a greater amount of urine still containing albumin.

On the forenoon of the 16th, Dr. Christie, Sr., saw the case

¹ Read before the Illinois State Medical Society at Springfield, Ill., May 15, 1900.

with me, and in the afternoon of the same day, Dr. Johnson also saw him. The first part of the day he was apparently better. Neither of the consultants was fortunate enough to see one of the facial spasms.

Two hours after Dr. Johnson and I saw him he began to grow worse. The spasms became general, tonic and clonic convulsions involving the entire body. Large doses of bromid and morphin failed to control them in any degree. In the 6 hours, from 3 to 9 P.M., he had between 30 and 40 convulsions, those occurring between 8 and 9 o'clock being so profound that at the climax of each, the attendants holding him in bed, thought the patient had died. There was opisthotonos, profound protrusion of eyeballs, tetany, recession of lips, face first congested, then cyanotic, then livid to an extreme degree. The pulse became very rapid and weak. The temperature was 99° and a fraction. Dr. Christie, Jr., now saw the case with me, and hoping it would afford relief, we determined to do craniotomy. Our diagnosis at this time was intracranial pressure, and we did not specify the cause.

The patient was placed on the kitchen table and the head prepared. I may say in passing, that the only scars upon the head were two linear ones, one above and behind the left ear, the result of a cutting affray some 10 years before.

No anesthetic was used, as the patient had been in a state of coma, between convulsions, for two or more hours. The opening was a curved incision of the soft parts over the middle and upper area of the right rolandic tract. A chisel was used for the bone work. The dura was very tense and bulging, with turgid bloodvessels. On incising it, considerable bloody serum escaped. The pia was so tense and protruding that, by the uncertain light of a hand lamp, it was first thought to be a cyst wall. Considerable blood, serum, together with small particles of gray matter, ran out when this was opened. The cortex was disintegrated so much that on touching it lightly with a gauze sponge, small pieces would adhere to the mesh. So far as exploration could be made, there was an appearance of multiple minute hemorrhages. The brain was aspirated in 3 different directions with negative results. The patient had 5 severe convulsions while on the table, a period of a little less than an hour.

It was decided futile to do more, so the wound was closed with absorbable sutures in the dura, and silkwormgut in the skin, and dressed with a good-sized gauze drain at each angle of the wound, one of them entering the dura. No effort was made to close the opening in the bone. The patient was placed in bed about 11 P.M., condition very bad, pulse 160 and very irregular. Prognosis the worst. Strychnin and atropin were given hypodermically.

There was no change until about 2 A.M., save that the convulsions grew more feeble, and came at longer intervals, which, considering his condition, I ascribed to approaching dissolution. At 2 o'clock the pulse had receded to 140 and was more regular. At 3 he was beginning to show signs of consciousness, with no convulsion since 1:30, pulse still improving. At 4 the patient was able to swallow a little brandy and water, and at 5 he began to speak. From this time he made an almost uneventful recovery. For about 30 hours after the operation the escape of serum was very copious, so great that not only the dressings but his pillows were kept saturated. Then the discharge stopped, and shortly after he began to complain of the pain in his head again, and later began to have slight spasms of the left facial muscles. I then dressed the wound, some 40 hours after operation. There was no serum escaping through the drains, but the skin over the opening was bulging. On pulling out the gauze that entered the dura a stream of clear serum shot up, like the spurting of a severed artery, to a height of probably 8 inches. An amount estimated at 3 ounces escaped. As some head-pain remained an hour after dressing I put 2 leeches on the postauricular space of the right side. Hereafter the wound was dressed daily, serum escaping for 8 or 9 dressings, when there being no more, the wound was allowed to close. Had it become necessary, aspiration could readily have been done through the soft parts. Six weeks from the time of operation he returned to his work, suffering no inconvenience. His employer tells me, however, that his perceptive faculties seem dulled, that he is indecisive, and slower of speech and motion than formerly.

The chief point of interest in this case is, perhaps, the difficulty thrown in the way of making a positive diagnosis. The majority of symptoms pointed to one or more of four diseases: Epilepsy, cerebral hemorrhage, cerebral thrombosis, and uremia—in other words eclampsia. There also presented for consideration the more unusual troubles, idiopathic nonsuppurative encephalitis and cerebral edema. Meningeal inflammation was not considered as a cause. Simple epilepsy was discarded because as time went by it became more and more evident that there was something more than functional trouble within the cranium. Traumatic epilepsy, in its restricted sense, could be eliminated since there was neither near nor remote trauma. Epilepsy from syphilitic neoplasm could not be considered if the word of the patient was good. On the other hand, there was a possibility of epilepsy from excessive mental or physical irritation. There was what might be considered a motor aura in the left hand, and the convulsions were epileptiform at least. Per contra there was a history of cerebral irritation of two weeks' duration, 11 days before this period of excessive physical and nervous exhaustion, and 14 days before any manifestation of *petit mal* or *grand mal*. There was an initial shock and a resulting hemiplegic condition. It was also evident that this intracranial irritation was rapidly growing more intense. These facts in their entirety, moved us to exclude epilepsy, per se, as a cause for the found condition.

The question of uremia with eclamptic convulsions then rose for consideration. Here was a case where the amount of urine had failed rapidly, and where upon examination it was found heavily loaded with albumin. The head-pain would not be out of place in an absence of kidney function, but there were no uremic vision symptoms. There was no vomiting. Instead of somnolence there was insomnia. The patient was a large, full blooded man, but his pulse was not unusually full or bounding. There was no uremic odor, nor urea crystals on the skin. Also, when kidney function and bowel action had been reestablished, after an apparent improvement of some 12 hours, the convulsions grew in frequency and intensity.

Uppermost, I believe, in the minds of the four members of the profession who saw this patient, was the belief in some form of cerebral hemorrhage. That it was slight, or at least insufficient to produce much pressure, was plain since there was no persistent paralysis. There was, first, the subjective evidence of intracranial irritation; then the objective evidence of monospasm, changing later to generalized convulsions; there was the shock, hemiplegia, and the patient's history.

Because of the train of convulsive symptoms it was believed that the lesion, or lesions, were near the cortex. It was not easy to reconcile the spasms of the left side of the face with a lesion of the right side of the brain, but some of the spasms were bilateral.

It may be impossible to prove to the minds of all that this was primarily a case of hemorrhage rather than embolism or thrombosis. I know of nothing more efficient for this purpose than the admirable table of differential probabilities, compiled by Church, of Chicago, and published in his work on Nervous Diseases and in the Year Book for 1899. Not all of these probabilities can be reconciled in this case, but enough of them can to make a somewhat unusual case reasonably clear. Thrombosis, according to him, is usual in young adults and in old age. Hemorrhage before 3, and between 40

and 60. This man was 36, but in habit, adipose development, and appearance is 40, or more. Church gives as the usual antecedents of thrombosis endarteritis, atheroma, endocarditis, cachexia, and embolism, none of which, we have reason to believe, were manifest here.

For exciting conditions of hemorrhage he gives high arterial tension, excitement, effort or shock, the reverse for thrombosis. In onset conditions this case is not so typical. Here was a prodromal period, not usual in hemorrhage, expected in thrombosis. The initial coma was of brief duration. The face was congested, the breathing heavy, and the pulse was full, though neither slow nor rapid. The motor loss was hemiplegic, and was greatest immediately after the initial shock. So, with the exception of the prodromata, these onset conditions coincide fairly well with those given by Church for hemorrhage.

Coming to his classification of symptoms for course, there was the expected rapid improvement in motion, the foot gaining faster than the hand. Anesthesia, however, was never marked, and periodical paresthesia persisted in part of the left hand, an anomalous condition. This patient never had true aphasia, but rather, tongue-sluggishness. Again, where this case was atypical was in the postplegic convulsions, they being classified as common with thrombosis, uncommon with hemorrhage.

I believe some of these anomalies may be accounted for by reason of the lesions being in, or near, the cortex. I have not been able to find much in current literature of value for comparison with this case. Bouffleur reports a case found unconscious on the street. As there was a scalp-mark of contusion, its origin and time of receiving unknown, it was thought he might have sustained a fracture, there being no other discoverable reason for his coma. At the operation no fracture was found, but there were present numerous punctate hemorrhages of the brain-substance. He classifies this as a brain-contusion.

The law laid down by Courtney is of interest since the operation in my case revealed cerebral edema. He says: "Cerebral edema is primarily the inevitable sequence in time, of that complex of pathologic symptoms which we designate contusion."

In the same connection, and bringing up a phase of the case hitherto dwelt upon. Traube says: "An acute edema of the brain produces uremic symptoms." The question then arises, Is it possible for this complex of pathologic conditions designated as contusion to come into being without violence exerted on the outside of the skull. I believe it is, that when a given arterial pressure acting under abnormal conditions, upon possibly an abnormal wall, of a given artery, is able to rupture that artery and cause a punctate hemorrhage, it is to be expected that this same arterial pressure will, under the same abnormal conditions, rupture adjacent walls of arteries of like abnormality and caliber, and cause multiple punctate hemorrhages. The rupture of a minute terminal twig is not like the rupture of one of the arteries outside of the cortical supply, for here the extravasation is so minute that arterial tension is practically unchanged, and, furthermore, these terminal twigs have no anastomotic branches. Whether or not, the curable encephalitis of Strümpell, called by some other writers cerebritis, a disease which produces a condition of the brain not unlike traumatic contusion, was present here during the two weeks of intense cephalalgia we cannot say.

In his work on nervous diseases Church says: "Except in traumatic cases, hemorrhage into the substance of the brain is a secondary or terminal effect of degenerative or inflammatory disease of the cerebral blood-vessels, almost invariably of the arteries." From his standpoint there existed in this case an inflammation prior to the rupture of bloodvessels, a condition designated by him as acute hemorrhagic encephalitis. He further says: "Anatomically the disease is marked by multiple, nonsuppurative, inflammatory foci, showing congestion and either punctate or massive hemorrhages, leukocytal infiltration, and localized destruction of brain-tissue." Still quoting, "most of these cases follow influenza."

We now have the tangle of symptoms made at least partly clear. First, the punctate hemorrhages revealed by operation, a brain trauma equivalent and analogous to brain contusion. Brain contusion producing brain edema (Courtney), the edema likewise demonstrated by operation. Acute brain edema producing uremic symptoms (Traube), one of the stumbling-blocks before the operation.

IDIOPATHIC PHLEGMONOUS GASTRITIS.*

By FRANCIS P. KINNICUTT, M.D.,

of New York.

Professor of Clinical Medicine, College Physicians and Surgeons, Medical Department, Columbia University, New York.

PHLEGMONOUS, or suppurative, gastritis is so rare a disease; and the number of cases,—including both the circumscribed and the diffuse forms,—reported in the literature of the subject is so small, that the presentation of a specimen with the clinical history of the case may be of interest to the members of the Association.

The earliest description of the disease would seem to be in a communication by Veranadeus,¹ in 1620. In the latter half of the seventeenth century and in the beginning of the eighteenth, there are published observations by Borel,² 1656; Sand,³ 1701; Vorwaltner,⁴ and Bonet.⁵ All of these observations describe the circumscribed form alone. Andral,⁶ 1839, and Cruveilhier⁷ appear first to have observed the diffuse form of purulent infiltration of the gastric walls. In their case only a fortunate accident led to incisions into the stomach-walls, which revealed a diffuse submucous suppurative inflammation. Since 1860 papers both on the circumscribed and diffuse forms have been published by Raynaud,⁸ Auvray,⁹ Leube,¹⁰ Hun,¹¹ Glax,¹² Lowenstein,¹³ Oser,¹⁴ Reinking,¹⁵ Kelynack,¹⁶ among others, and, finally, a very admirable monograph by Leith,¹⁷ of Edinburgh, in 1896. Leith¹⁷ has been able to collect only 51 positive cases of the diffuse form in the entire literature of the subject, and the total number of cases both of the diffuse and the circumscribed forms is given as 85. For a very interesting discussion of the entire subject especially, I would refer to Leith's¹⁷ monograph.

The specimen which I present is an exquisite example of the primary diffuse form of the disease. A single other instance of a similar form came under my observation many years ago in the wards of Bellevue Hospital, in which the true lesion was only demonstrated at autopsy.

CLINICAL HISTORY.—M. L., male, aged 41, plumber. Admitted to the Presbyterian Hospital, April 10, 1900. Service

* Read before the Association of American Physicians, Washington, May 1900.

of Dr. Kinnicutt. Family history unimportant. *Previous History*: There is no history of syphilis. An alcoholic habit has existed for many years. The patient states that he has never suffered from gastric disturbances, except at times of excessive drinking, and has enjoyed excellent health. *Present Illness*:—Five days before admission to the hospital, after drinking to excess and after a hearty meal, he suddenly began to vomit. The vomited matter consisted at first of the food in the stomach, and later of a brownish fluid. Vomiting occurred frequently during the four subsequent days, irrespective of the ingestion of food, which was only fluid in character. There was never any blood in the vomited matter. There was moderate diarrhea for the first three days, and then no further movement of the bowels previous to admission. Blood was not present in the stools. With the onset of the vomiting he suffered from pain located in the epigastrium and in the lower abdomen. The pain was acute and more or less constant for the first three days. For the two days previous to admission, he was comparatively free from suffering. With the occurrence of the first symptoms of his illness, there was a feeling of chilliness, but no distinct chill.

Examination on Admission.—The patient is a large muscular man, well nourished, and not anemic in appearance. The tongue is very dry and moderately coated. The respirations are shallow, 48 to the minute. The pulse is 108, full, and a little tense. Temperature (rectal) 101°. The patient is very restless, anxious, and obviously very ill. Heart: The apex is in the fifth space in the mid-clavicular line. The left limit of cardiac dulness in the fifth space corresponds with the apex impulse. No murmurs are appreciable. Lungs: Negative, beyond slight dulness at both bases and moderate subcrepitation over these areas. Liver: Percusses from the sixth rib to the costal arch in the mid-clavicular line; edge not palpable. Spleen: Area of dulness not increased, edge not palpable. Abdomen: Is moderately distended with considerable rigidity of the abdominal walls, most marked in the upper half. There is moderate sensitiveness on deep palpation and slight on gentle palpation, and this sign is not obtained uniformly over the abdomen, but at several points, being most marked over the epigastrium and right hypochondrium. It has been noted that the liver-dulness is not obliterated, but fully reaches the costal arch in the mid-clavicular line. Over the liver-region, just above the costal arch, and also over the left hypochondrium in the anterior axillary line, scanty crepitation is heard, and is believed to indicate an involvement of the peritoneum. Signs of free fluid in the peritoneal cavity are not obtained. Abdominal respiratory movement is present, but diminished. The urine is free from albumin and sugar; specific gravity, 1.025. It contains a few hyalin and granular casts.

Lavage was immediately given and a yellowish-brown fluid, without odor, considerably larger in amount than that introduced, was returned by siphonage. A general peritonitis was believed to exist; the causative lesion was judged to be either an acute pancreatitis or a perforating ulcer of the duodenum.

On consultation with my colleague, Dr. McBurney, an exploratory laparotomy in the pyloric region was decided upon. The patient's condition, however, so rapidly became worse, the heart very suddenly failing, that surgical interference was not deemed advisable. Death occurred 16 hours after admission. Large quantities of a yellowish-brown fluid were repeatedly vomited during this period. The patient suffered little pain, and there were no further symptoms other than those of collapse.

AUTOPSY.—*Anatomical Diagnosis*: Diffuse Suppurative Gastritis; General Peritonitis.—Frame, large; adipose, considerable; muscle, fairly developed. Heart: weight 12½ ounces. Pericardium normal; valves, normal; muscle, normal. Lungs: moderately congested at bases; a few old adhesions of pleurae. Liver: weight, 73½ ounces. Firm in consistence, surface deeply congested in places, for the most part pale. On section, pale, otherwise normal in appearance. A few old adhesions present and some recent fibrin. Gallbladder: filled with pale brown, very viscid bile. Spleen: weight, 5½ ounces; surface smooth; consistence soft. On section,

coarsely mottled, pale and dark red. Pancreas: normal in appearance and on section. Adrenals: normal in appearance and on section. Kidneys: left, weight 6½ ounces; capsule adherent, surface smooth. On section, normal in appearance. The right kidney is similar in weight and appearance to the left. Ureters, bladder, prostate, and seminal vesicles, normal. Abdomen: the peritoneal cavity contains a moderate quantity of turbid fluid. There is a small amount of fibrinous exudate adhering to the surface of the peritoneum at various points. The omentum is adherent to the mesentery by firm, slender bands, across which hang some loops of small intestine. Stomach: normal in size. Its walls are greatly thickened, extraordinarily so in the pyloric region. On section, the thickening is seen to be due to a purulent infiltration of the submucosa. At the pylorus and to a point 3 inches from it, the thickness of the submucosa throughout the circumference of the walls is fully an inch. Elsewhere its thickness is a little less, and is very uniform. The process is sharply limited at the pyloric ring. Not so at the cardiac orifice, where it extends upward to a point about 2 inches from the orifice. The infiltration is of a yellowish white color, and is firm and solid; only a little watery fluid exudes on firm pressure. It separates the mucous from the muscular coat with great distinctness, both of these coats standing out prominently on either side of it. The surface of the mucosa is uneven and, in places, greatly congested, especially near the cardiac end. The muscular coat is slightly swollen. On the posterior wall of the stomach, near the lesser curvature and 3 inches from the pylorus, there is a linear cicatrix, 1½ inches in length. At the lower end of the cicatrix, there is a small area, necrotic in appearance.

MICROSCOPIC REPORT FROM THE PATHOLOGICAL LABORATORY OF THE HOSPITAL, BY DR. BERKELEY.

Minute Anatomy of the Stomach-wall.—Tissue hardened in formalin and alcohol, mounted in celloidin, stained with the usual reagents.

The *Mucous* and *Subserous Layers* show irregular thickening and infiltration with round cells. The endothelial covering is in most places entirely lost.

Muscular Coat.—The fibers of the muscular layer are swollen and much distorted. The connective framework is everywhere crowded with leukocytes. These leukocytes are of unusual size, are mainly mononuclear, and the nuclei are as a rule round, more rarely crescentic or irregular. There are a few apparently polynuclear forms. Some of these have penetrated even between the individual muscular strands.

Submucosa.—This layer is enormously thickened, measuring in certain places three-fourths of an inch even in the hardened section. It has evidently been the main seat of the bacterial infection. Its fibers are widely separated by quantities of fibrin, leukocytes, lymphocytes, and complete *strata* of bacteria (see below). The violence of the inflammation has caused extensive areas of partial or complete necrosis; in these only the faintest outlines of cells and fibrils are distinguishable. The lymphatics are here and there gorged with microbes. Between the submucosa and the mucosa proper the necrotic spaces are less numerous, but vast numbers of lymphocytes (many more than those normally present) are found. The *muscularis mucosae* is generally in place, and unexpectedly enough seems to have participated in the pathologic process less than any other layer of the entire stomach.

Mucosa.—This is preserved in a few places. Here the peptic glands are in various states of inflammation and degeneration. The nuclei of the glandular cells stain everywhere ill or not at all. The protoplasm is markedly granular. In other portions the mucosa is eroded, or necrotic, or quite absent. Sections made through the necrotic part of the old cicatrix referred to in the description of the macroscopic appearances (by Dr. Kinnicutt) show that at one point the infiltrated submucosa is completely exposed by a deep erosion in the inflamed and necrotic mucosa. Whether or not this was the point of original pyogenic infection does not, of course, admit of demonstration; such a hypothesis, however, seems reasonable.

In respect of the anatomic extent of the inflammation, it is rather strange that while the phlegmonous

swelling is perfectly and clearly delimited on the left by the pyloric valve of the stomach, the lower (cardiac) end of the *gullet* has not escaped; the latter shows for some distance upwards practically the same changes found in the stomach-wall, viz., swelling, softening, intense cellular infiltration, and a countless number of microorganisms. Through the stomach itself the infiltration is universal, and the degree of swelling is high everywhere.

The bacteriologic examination shows the practically universal presence of a streptococcus. It is most abundant in the connective tissue of the submucosa and muscularis. Some of the individual chains are quite long, being made up of eight and ten members. Most are shorter. Contrary to the classic descriptions, few or no cocci are to be found inside the leukocytes. The *strata* mentioned above are made up almost entirely of these chain cocci. The lymphatics contain not so many cocci as bacilli. The latter are long, with deeply stained ends (spores?). They are possibly of *postmortem* origin, inasmuch as they are abundant in the superficial vessels. No cultures were made from the stomach, but films made from the exudate on the cut surface show that the streptococcus is the prevailing pathogenic organism.

ANEURYSM OF SPERMATIC ARTERY SIMULATING OBLIQUE INGUINAL HERNIA.

By S. W. MILLER, M.D.,
of Lancaster, Pa.

Medical Superintendent Lancaster County Hospital.

THE following record of a case is reported mainly on account of its closely simulating a hernia, and also on account of the large size of an aneurysm of so small an artery, and the subsequent gangrene which occurred.

The blood-supply of the testicle and its excretory duct, which is derived from the spermatic and vas deferens arteries, both of which accompany the spermatic cord, was occluded by the aneurysm in the one, and the pressure at the internal ring on the artery to the vas, by the aneurysm. The blood-supply to the scrotum is derived from the superficial and deep external pudic, the superficial perineal, and the cremasteric arteries. Owing to the weakened physical condition of the patient and the pronounced disturbance of the circulation and the underlying gangrenous testicle, these arteries were unable to provide the necessary nutrition, and the scrotum, as well, took part in the gangrenous process. A report of the case follows:

P. S., aged 62; of German nativity, laborer, was admitted to the hospital April 4, suffering with mitral regurgitation and cardiac asthma, with marked edema of the lower ex-

tremities and all the associated symptoms of failure of compensation. Examination of the urine showed no albumin nor sugar present. Tincture of digitalis in 15-drop doses every 4 hours was prescribed. On the evening of the 5th, the day after admission, the nurse accidentally noticed a swollen and dusky red scrotum on the right side. I learned that the patient had not complained of any pain whatever in this region. Upon examination I found a sausage like tumor extending along the length of Poupart's ligament and down into the scrotum, which was swollen to the size of an orange. The skin and underlying tissues were of a dark bluish color, and there was some tenderness about the internal abdominal ring. The gross appearance was that of a strangulated inguinal hernia. There had been no vomiting, but a number of small stools accompanied with much tenesmus. The patient had been wearing a truss for a right inguinal hernia for some months.

Operation was advised, and early in the morning of the 6th, before operating, I again examined him, and found that the scrotum was already black and gangrenous. He had grown much weaker, the tongue was brown and dry, some delirium had been present, and the pulse was frequent, lacking in force and volume, and a condition of sapremia existed. The temperature had been slightly subnormal.

I cut down over the cord, and removed the scrotum and testicle, which were both gangrenous, and followed up the cord to the internal ring, where it was amputated, the whole length of it being necrosed. There was no intestine nor omentum in the canal. After packing with iodoform gauze the incision was partially closed with silkwormgut.

The operation was of no benefit, however, and the patient died late the same day.

At the autopsy there was found a tumor about the size of a goose egg, of a purplish color, of the consistence of gelatin, situated behind the peritoneum. The surrounding peritoneum was red and injected. This tumor, which proved on close inspection to be an aneurysm of the spermatic artery, was presenting at the internal abdominal ring, around which there were some few adhesions. Upon section, a large current-jelly clot was found filling up the whole of the aneurysm.

NOTE ON SPECIMEN SHOWING A SMALL SACCULAR ANEURYSM ON AN ACCESSORY BRANCH OF THE RIGHT RENAL ARTERY.

By MAUDE E. ABBOTT, B.A., M.D.

Assistant Curator Pathological Museum, McGill University, Montreal, Canada.

A SPECIMEN of renal aneurysm in the Pathological Museum, McGill University, presents another example of this rare condition, attention to which has recently been drawn by Professor Keen in the *PHILADELPHIA MEDICAL JOURNAL* for May 5, 1900. As seen in the photograph, the aneurysm is situated on an accessory branch of the right renal artery, just beyond its origin. It presents a small excrescence, the size of a marrowfat pea, on the posterior surface of the vessel. The sac wall is smooth externally. On section it cuts toughly and is seen to be thin above, but thickened at its proximal end by the deposit of fibrin which gives it a laminated appearance. At this point also there is beginning fatty degeneration of the wall. The sac contents consist of a single firm blood-clot, forming a rounded mass which lies free in the cavity, almost filling it. The clot is homogeneous in structure, not laminated. The renal artery as also the abdominal aorta show beginning atheromatous degeneration. The kidney is large, weighing 175 grams and microscopically shows a chronic interstitial nephritis. So small an aneurysm naturally gave rise to no symptoms during life, so that only a few points will be of interest in connection with the history of the case:

The patient was admitted to the Royal Victoria Hospital June 27, 1898, in the service of Dr. James Stewart.

whom we have to thank for permission to make the following notes from the clinical report: She was a multipara, aged 56, giving a history of moderate alcoholism, but no history of inherited disease. Two years ago she fell heavily, injuring her back, and has never felt well since; 18 months ago she had an attack of subacute rheumatism. Six months ago she sustained another heavy fall. On entrance to hospital she complained of weakness, shortness of breath, swelling of the legs and abdomen, loss of flesh, and sleeplessness. These symptoms set in about a year ago but have increased greatly during the past two months. The urine was dark-colored, acid, specific gravity 1.020, containing bile and a small amount of albumin. Casts were not certainly made out.

The postmortem was performed by Professor Adami, who preserved the specimen for the museum. The following notes are abstracted from the report made at the autopsy:

There was general anasarca of the body, ascites, right hydrothorax, edema of the lungs, early cirrhosis of the liver, and advanced chronic interstitial nephritis. The heart showed slight fibrosis of the mitral valve. There was beginning atheroma, slight in the aorta, more marked in the medium and smaller-sized arteries, the branches of the renal arteries being distinctly calcareous. The spleen showed one small and one large white infarct. Both kidneys were hog-backed in type. There was extensive scarring of the left kidney and at its lower apex a small well-defined white infarct. The right kidney showed four cicatrices and microscopically advanced chronic interstitial nephritis with marked periglomerulitis and atrophy of the tubules. In the medulla were hemorrhagic areas.

With regard to the etiology of renal aneurysm, in the 13 cases collected by Professor Keen in his article, to which reference has been made above, there was a history of trauma in 6 cases; of nephritis in 2; of calcareous degeneration of the arteries in 2, and of chronic endarteritis in 1. In 4 cases, including the one operated on by Professor Keen, no assignable cause was made out.

In our case it is interesting to note that not only was there a chronic nephritis present, and some atheroma of the vessels, but there was also a history of trauma two years previous to death—"A heavy fall in which the patient injured her back." Any or all of these three conditions may have been in operation causing the aneurysm.

VENOUS THROMBOSIS IN HEART-DISEASE.¹

By WILLIAM W. FORD, M.D.,
of Montreal, Can.,

Fellow in Pathology, McGill University, Montreal.
(From the Pathological Laboratory of the Royal Victoria Hospital.)

WELCH, in his recent paper on venous thrombosis in heart-disease, read before the Association of American Physicians in Washington, has called attention to this complication in cardiac disorders. In his paper he has given abstracts of all of the cases which he could find recorded in the literature. He states, moreover, that he considers the thrombus to be microbic in origin, and has referred briefly to a number of cultures which have been taken from thrombi in the pathological laboratory of the Johns Hopkins Hospital.

The following case, which occurred in the wards of the Royal Victoria Hospital, represents this condition, but unfortunately no cultures were taken from the thrombus at autopsy:

D. Bonnar, aged 56, blacksmith, was admitted to the hospital December 18, 1899, and died February 18, 1900, under the charge of Prof. Stewart. The patient gave a history of acute rheumatism when a young man, involving ankles and wrists and knees, and 12 years ago an attack of pleurisy with lumbago and phlebitis. For the past two months has had increasing dyspnea, anorexia and edema of the legs, attacks similar to which he has had since onset of his first trouble.

On admission the patient was in labored respiration, quite cyanotic, pulse irregular in volume and rhythm; heart-dulness increased with definite signs of mitral insufficiency; numerous moist rales throughout chest. Five days after admission a hard, tender mass about the size of a half-dollar was felt about the saphenous opening on the right side of the right thigh, and extending from this point round to the inner side of the thigh was felt a small tense vessel. There was, as well, a tender point felt in the popliteal space along its inner side to about the middle of the calf, where there was decided tenderness and pain on pressure.

The symptoms of cardiac insufficiency increased, the pulse became very weak and irregular; patient suffered from great dyspnea and was at times delirious. On January 10, 34 ounces of clear, straw-colored fluid were removed from the right pleural cavity. The cardiac dulness, however, continued to enlarge, the heart showed signs of muscular breakdown; there was marked edema of the legs and blood-stained expectoration.

At autopsy, performed by Dr. Adami, there was 1,600 cc. blood-stained fluid in the right pleural cavity, general anasarca and edema of the extremities. The heart was found to be very much enlarged, pericardial cavity contained 100 cc. of clear, straw-colored fluid. The mitral valve was contracted, its edges markedly thickened without calcification of mitral ring. The mitral orifice showed a slit-like opening about 2.5 cm. in diameter. The left ventricle was greatly enlarged. In the lungs on the right side the lower middle lobes were converted into an enormous infarct, the right pulmonary artery being blocked by an embolus, which with the succeeding thrombus entirely shut off the circulation from this part of the lung. Abdomen and abdominal organs normal. The right common iliac vein showed an old organized thrombus throughout its whole extent, surrounded by numerous bands of adhesions the lower end of the vein gradually tapering down until it became a small, thin strand of fibrous tissue. At the junction of the femoral and the internal saphenous veins the vessel was completely blocked and showed a very recent thrombus filling in that portion of the lumen not already occupied by the old organized mass. At the saphenous opening the saphenous vein showed a sudden fusiform enlargement, the external diameter at this point being 15 mm. About this thickening there was considerable fibrinous periphlebitis, the main veins and branches were completely obliterated by thrombi, firm, and apparently of some standing, but still red in color. The internal femoral cutaneous veins as well were completely thrombosed, rigid and firm, standing out like hard cords.

VOL. VI, No. 21

NOVEMBER 24, 1900

\$3.00 PER ANNUM

Secrecy and local patriotism, when it concerns infectious disease, may prove to be a great source of danger to the country. It is this fact that gives those who believe in the national control of quarantine their strongest argument. We wish distinctly to avoid arousing local feeling, but the duty of arousing the alertness and protecting the interests of the entire country is more incumbent upon us. It would be easy to give examples of the evil in the past, and even in the present, if any good service could thereby be rendered the entire community. We know today, for example, that yellow fever exists within the bounds of perhaps more than one of the United States, disguised under other names. We have such sympathy with the inhabitants that we can realize the tragedy that would befall them should this fact become known. Whenever the deceit is not coupled with the most stringent local measures to stamp out the disease, the evil at once and most decidedly becomes of national significance. But we hate the secrecy and the deception, and we believe that in the long run it is as bad policy as it is bad morals.

The medical inspection of schools is a measure concerning whose utility there can be no two opinions. Of its eminent success the results of its operation in the city of Chicago, as made public by the Health Commissioner, Dr. Reynolds, afford demonstrative evidence. Of 75,000 children examined in the course of eight school months, 4,539 were temporarily excluded from school on account of contagious disease. As a result, the mortality from scarlet fever and diphtheria has been reduced almost one-half. Authoritative information is wanting as to the results obtained in the city of Philadelphia from similar examination of school-children, but there can be no doubt that a marked lessening in the prevalence of the contagious diseases has been thereby effected, and that many lives have been saved in consequence. While the plea was at first made that the undertaking was in the nature of an experiment, and that it would not be wise at the time to apply for an appropriation for the services of the examining physicians, the hope was held out that if the plan proved practicable and useful, at least nominal remuneration would be provided for those who had most contributed to the success of the movement. It now appears that there is some unwillingness to appropriate

the necessary money for the purpose. This should not be, but reasonable compensation should be given for work requiring special skill and acumen, and having direct material value. We pay men for securing public safety, for the extinguishment of fires, and for multifarious other purposes, and we should not attempt evasion of payment for the prevention of disease and death.

Cataract "Absorbers."—Many years ago there was a good deal of newspaper gossip of the pseudo-scientific sort as to the absorption of cataract by drugs used internally or applied locally. The ophthalmologists soon silenced the nonsense until of late, when it seems to have been galvanized into life by much the same class of people who were interested in it formerly. We have heard something of institutions exploiting such remedies and making extravagant claims as to their powers. When newspapers publish the reports of cures of cataract or advertisements claiming to cure, they perhaps have no conception of the suffering and waste of money they cause. There is, indeed, a class of so-called physicians who either through deplorable ignorance or more deplorable shamelessness delude patients with the silly hope that drugs and applications can "dissolve" or "absorb" cataract. We believe that cataract may be prevented and its progress sometimes retarded, or even brought to a standstill, by the relief of eyestrain. But to humbug patients with the false belief that an existing cataractous lens can again be made transparent by drugs is wanton cruelty and downright quackery.

Suicide in the Army.—Surgeon-General Sternberg has recently been investigating the subject of suicide in the U. S. Army. He has selected the years 1898 and 1899 for comparison with the ten years between 1888 and 1897. The first mentioned two years, it will be observed, constituted a period of greatly increased activity in the army owing to the war in Cuba and the Philippine Islands. During this period also the size of the army was greatly augmented. In view of these facts it is noteworthy that there were relatively fewer suicides in the army during these two years than during the preceding decade. The average number of suicides per year in an army of 27,116 men for the ten years was 17. This was a ratio of .063%. The strength of the army in

1898 was 147,795, and the number of suicides was 38, or .026%. In 1899 the strength of the army was 105,546 and the number of suicides was 30, or .028%. If any deduction is warrantable from these figures it would seem to be that actual warfare, and even mere increased activity in the field, tend to diminish the number of suicides in an army. This would probably be accounted for by the improved mental hygiene that comes with an active life, change of scene, keen interest, and the intense emotional excitement incidental to actual war. The statistics do not appear to prove that military service in the Philippines has been the cause of increased mental disease.

Suicide among soldiers has been a subject of special interest for many years in European countries, and special treatises have been written on it, notably the theses of Cristan in 1874, and of Mesnier in 1881. Wallmann, in 1858, furnished some figures derived from the Austrian Army. He found that about 66% of these suicides shot themselves, but these figures probably do not hold everywhere. The next commonest method was hanging. The men were comparatively young. The causes, as observed by Wallmann, were fear of punishment, dislike for a military life, homesickness and melancholia, dissipation of various kinds, debts, wounded honor, and bodily suffering. In the Prussian Army in recent years, suicide is said to have been on the increase, and some persons have attributed this increase to the rigor of the service and the severity of the discipline.

Plague in San Francisco.—The exact truth should be known about the prevalence and prospects of plague at any place in this country, and therefore we welcome an official statement made by Dr. J. J. Kinyoun, of the U. S. Marine-Hospital Service, respecting the state of plague in San Francisco during the month of October. Three cases of the disease, all fatal, occurred among the Chinese in that city. The first case was in a cigar-maker who had been plying his trade up to the very moment when he was taken ill. No clinical history could be obtained, and the real nature of the disease was only discovered at the autopsy. The plague-bacillus was found in the enlarged femoral glands. The second case occurred in a house already infected by a fatal case in July. The death-certificate gave "typhoid pneumonia" as the cause of death. A mass of enlarged femoral glands were discovered, and the plague-bacillus was demonstrated. The third case was quite a typical one, and the diagnosis was made before death. The enlarged spleen and enlarged femoral glands were thoroughly infected with the bacillus. The coverslips made from the fluid removed from these glands contained countless bacilli; in fact, the preparation looked more like a pure culture than a pathologic specimen. Animal inoculations were in every way confirmatory.

Dr. Kinyoun states his belief that the area of infec-

tion in San Francisco is gradually growing wider, so that now there are only 3 blocks of the Chinese quarter proper in which plague has not occurred since last March. The conditions which will obtain in the next six months will, in his opinion, be conducive of a further outbreak. The Chinese population in San Francisco is largely augmented in the winter months. From the salmon fisheries of Alaska alone about 3,000 Chinese return every fall. Then at the end of the fruit-picking season many more of these people flock to San Francisco and make it their home during the winter months. They are of the lowest coolie class, and live amidst the worst possible hygienic conditions. Dr. Kinyoun fears, very naturally, that this population will supply the soil for plague, and we argue with him to the extent, at least, of thinking that the situation has its grave risks. Under date of November 6, Dr. Kinyoun reports still another case of plague, this time most unfortunately in the person of a trained nurse. This nurse had been in attendance on a case of supposed diphtheria, but the bacteriologic examination left no doubt of the nurse's own case at least being plague. This case did not occur in Chinatown. Dr. Kinyoun believes that other cases of true plague occurring in San Francisco are being reported under other names. The situation thus depicted is not to be winked at or covered up. The whole country is interested in San Francisco's health just now, and will insist that it be carefully looked after.

The Census.—The Twelfth Decennial Census of the United States will doubtless contain many interesting statistics for the medical observer, but it is too early yet to obtain them. The preliminary statement, recently given out, places the whole population of the country, including Hawaii, at 76,295,222. Only three countries, China, Russia, and the British Empire, surpass this republic in number of inhabitants. Regarding this country simply as a field for medical research these numbers are indeed stupendous. They mean that, with our energetic and advancing population, we have in the United States a territory of unrivalled opportunity and productiveness for the cultivation of the medical, hygienic, and sociological sciences. Some of the figures are significant. The rate of increase has been about 21%, which means that 13,225,464 have been added to our population since 1890. This rate, however, is lower than that of any decade since the first census of 1790, and this fact seems to indicate that natural causes are operating, according to the laws of population, to curtail in a measure the former phenomenal growth of the country. We may, therefore, reflect that the time has come when the problem is no longer one of mere growth, but of assimilation and cultivation. We may no longer expect excessive growth, but we must be prepared to elaborate what we already have. From a medical standpoint this thought furnishes

much food for reflection. The lusty infant has become a grown man; he must now put forth his strength, and learn to know himself and to meet his destiny.

New York State still leads with 7,268,000 people. Pennsylvania comes next with 6,301,365. But local pride may take a modicum of satisfaction in the fact that if the population of the two cities, New York and Philadelphia, be subtracted, the State of Pennsylvania has the larger population, and is truly the Empire State. Illinois, with 4,821,550 inhabitants, is third, and Ohio, with 4,157,545, is fourth. These four States combined would constitute a respectable "empire," and exceed the combined population of the United Kingdom and the United States 100 years ago.

From the medical standpoint a fact of great interest and importance is the growth of urban population. The increase in cities of 25,000, or more, has been more rapid than during the preceding decade; in other words, there is no reaction from the tendency of the American people to live in towns. We are becoming more and more a nation of town-dwellers. This fact shows at once how important among us have become the problems of civic righteousness. These problems, indeed, have become foremost in our social life, and not least among them are the problems of medical and hygienic science. Whether this tendency is for good or for evil may be a debatable question, but the fact is before us and we must meet the obligations which it imposes.

The Present Status of Litholapaxy.—An examination of the literature leads one to the conclusion that litholapaxy has not received, in this country, the recognition to which it is entitled, except by a few surgeons. It is an especial pleasure, therefore, to observe the high estimate placed upon this operation by the surgeons of India, whose enormous experience entitles their views to the most respectful consideration. A most impressive exposition of this subject appears in the "Special Stone Number" of the *Indian Medical Gazette* (August, 1900), from which the following quotations and statistics are taken:

It may be said without fear of successful contradiction that the operation of litholapaxy, in its conception and final execution, will ever stand as one of the most brilliant achievements in the entire field of surgery. It was introduced by Professor Bigelow, of Boston, in 1878, and was immediately taken up by the more progressive surgeons of this country and Europe. Previous to this time stone in the urinary bladder was dealt with either by lithotomy or lithotrity. The latter had already become with some surgeons the operation of choice in selected cases, but it was attended with such serious inconveniences that many hesitated to adopt it. The instruments employed for crushing the calculi were inefficient and unsuited for their work, and the irritation caused by the fragments passing with the urine

was considerable. Besides, recurrence was common on account of the fact that some of the fragments remained in the bladder and became the nuclei of new concretions. That these inconveniences, not to say dangers, impressed those of the largest experience with vesical calculi is shown in a volume on lithotomy, based on 864 operations, published in 1876, by Surgeon-Major Harris, of the Bengal Medical Service. In the preface the author says: "No reference has been made to lithotrity, as I, following the general custom of surgeons in India, have never practised it." As already stated, litholapaxy was brought out in 1878. That the operators of India were impressed with the merits of this method of dealing with stone is evidenced by the fact that it was performed by Surgeon-Major Beaumont, in 1880.

In the *Indian Medical Gazette* for 1882-3, Surgeon P. J. Freyer records his first 20 cases. In the same journal for March, 1884, he says: "I cannot speak in terms of too high praise of Bigelow's operation. By its introduction the operative surgery of stone has truly been revolutionized." In 1892, Dr. Keegan writes: "I have no hesitation in stating that it is far and away the best operation for the vast majority of the calculi the surgeon meets with in boys, provided he has a large assortment of trustworthy instruments to hand and that he knows how to use them with dexterity and judgment." The weight of the testimony of almost all of the Indian surgeons today is even more strongly in favor of this procedure. To quote the opinions of the various operators would require far more space than could be devoted to this subject, and, moreover, would be but a profitless repetition. The consensus of opinion appears to have been expressed by Freyer in the *British Medical Journal* for November 7, 1896. He says: "With results such as these before me, I have no hesitation in pronouncing Bigelow's method the safest and best for calculi of all sizes, in patients of all kinds and conditions, provided only that this operation is feasible. . . . So fully convinced am I of the vast superiority of Bigelow's operation over all others in saving human life and suffering, that I would lay it down as an absolute rule, that in no case, whether in the male or in the female, the adult or the child, should a stone, whether small or large, be subjected to a cutting operation till after trial litholapaxy is found to be not feasible."

Let us consider for a moment the experience upon which these opinions are based. Keegan reports 500 litholapaxies performed on boys at the Indore Charitable Hospital. The average of these patients was 6 years; average weight of stone, 95 grains; average stay in the hospital, 4 days; mortality, 2.2%. Henderson has performed 1,200 litholapaxies, but does not speak of his results, as the paper deals only with "perineal" litholapaxy. At the Mayo Hospital, Jaipur, 175 litholapaxies have been performed during the past 5½ years with a mortality of 1.7%. The ages of these patients ranged from 7 months to 80 years. The average stay

of the patient in the hospital was 6 days. Baker refers to 404 cases published in the *London Lancet*, in 1896 and 1897. The mortality in these cases was 0.742%. The extremes of ages were 8 months and 78 years. Many other similar experiences might be quoted. At least three medical officers in India have reported series of over 100 consecutive litholapaxies without a death. For the 5 years, preceding March 31, 1895, the record of all Indian litholapaxies was 10,073 operations, with a mortality of 3.96%. The mortality in 7,201 cases of lateral lithotomy by the same operators, was 11.02%, while 147 cases of suprapubic lithotomy was followed by a mortality of 42.17%. It should be said of the suprapubic cases that they represented the most unfavorable examples met with, hence the high death-rate.

The majority of surgeons of this country have accorded litholapaxy a restricted place in dealing with stone. In most textbooks a number of contraindications to the operation are mentioned. Chief of these are: Persons below the age of puberty, very hard stones, very large concretions, stricture of the urethra, enlarged prostate, stone of the bladder, encysted stones, a sacculated condition of the bladder, cystitis, etc. A few operators have reduced this list by half or more in their practice. That this number should be still further curtailed is shown by the work of the Indian surgeons. To meet the cases of "hard" and "large" stones, and stricture of the urethra, "perineal" litholapaxy was introduced by Brigade-Surgeon Forbes Keith, at the time Civil Surgeon of Hyderabad, Sindh. This consisted in the addition of Bigelow's operation to the method of Dolbeau and of Harrison, the difference being that Keith opened the membranous urethra and passed the lithotrite and evacuators into the bladder by this route. By this means larger and much stronger instruments may be employed without injury than could possibly be manipulated through the urethra. The prostate and vesical neck not being incised, perfect control of the sphincter remains, and the small wound heals in a very much shorter time than the usual lithotomy wound. The statistics of this operation are few, as but a very limited number of the hospitals possess the necessary instruments. Henderson reports 110 cases; of these 13 were in adults; all recovered, and 97 were in children. Three were fatal giving a mortality of 3.09%, or for the whole, 110, 2.73%. It must be remembered that these were unsuitable for urethral litholapaxy, and yet the showing is nearly as good as that obtained in uncomplicated cases. This was the first improvement in Bigelow's operation, or, to be more correct, extension of the method. The next, and only other addition to this work as Bigelow left it was by Forbes (*Medical News*, June 23, 1894), who demonstrated with mathematical precision the resistance of vesical calculi to crushing force, and the strength of the lithotrite. From these factors and a careful considera-

tion of the lithotrite from a mechanical standpoint, he devised a new instrument which is stronger and more efficient than those hitherto employed. Each lithotrite is tested before being sent out, and the pressure it has withstood is plainly stamped upon it. A mechanism in the handle indicates to the operator the power he is exerting between the jaws of the instrument so that he may be certain of the amount of force he may safely apply. By this means, broken and bent lithotrites which have constituted rare, but serious complications of litholapaxy, will be unknown. The Forbes instrument being more powerful than the other types in use of equal size, resort to the perineal route will be less frequently necessary.

How well Bigelow accomplished his purpose is shown by the fact that today, save the single improvement of Forbes, his instruments and his methods have not been advanced in a single particular. It is most exceptional that the first effort approaches so nearly perfection.

The operation of litholapaxy may be considered ideal. The work of Bigelow has added a luster to American surgery that will endure as long as the healing art is practised. To American ingenuity also belongs the credit of bringing the lithotrite to a higher degree of efficiency.

Plague.—The last of the plague patients has been discharged from the Plague Hospital, at Glasgow, and the port has been declared free of the disease, and clean bills of health have been allowed to vessels leaving the harbor. The outbreak has extended over a period of nearly 3 months, and 28 cases have been dealt with, 8 of which terminated fatally. Fully 170 "contacts" have passed through the reception houses, over 120 being under observation there at one time. At a recent meeting held in National Hall, Glasgow, Dr. Thomas Colvin advocated the appointment of a port medical officer. The Tynemouth Hospital and the Tyne Floating Hospital, specially set apart for plague patients, have each a case of suspected plague. Up to the present, however, the diagnosis of plague has not been confirmed. The mortality from plague for all India increased from 2,123 during the week ended October 7, to 2,322 during the week ended October 14. In the Bombay Presidency the deaths from plague during the same periods rose from 1,142 to 1,415. In Calcutta the number of cases of plague has fallen most satisfactorily.

Important modifications in the existing plague regulations have been made by the Government of Bengal. The rules issued in 1898 have been cancelled, their place being taken by regulations of a simpler nature. Isolation, segregation, and inoculation are to largely give place to sanitary and disinfecting precautions, so as to avoid every chance of friction with the natives, and of fighting against their superstitions and prejudices. In Bangalore, plague has increased rapidly, plague corpses being found cast away in the municipal drains, etc. In Mysore, there has been a slight decline in the plague mortality. In the Kolar gold fields the fresh outbreak of plague has caused considerable alarm. For the present it is confined to the Coromandel gold mine and to a village adjoining the mine. The infection is supposed to have been conveyed through a supply of flour imported from Bombay. The plague in Poona City shows no signs of abatement. The exodus from the city continues, and Poona seems to be once more in the throes of a severe epidemic. From the Island of Mauritius, 50 fresh cases of plague were reported for the week ended November 12, with 34 deaths. United States Vice Consul General Knight, at Capetown, South Africa, has informed the State Department that plague is declared officially to exist in the interior of the colony. The information was communicated at once to the Marine-Hospital Service.

Reviews.

The Care of the Child in Health. By NATHAN OPPENHEIM, A.B., M.D. New York: The Macmillan Company, 1900.

There need be no hesitancy on the part of physicians to recommend this book to parents, for it does not go beyond its title more than to be a guide as to when medical attention is necessary. No parent and we might say no adult, can fail to be benefited by reading the chapter on the "Relation of Parents to Children." The advice throughout the book is uniformly sound with the exception of a few slips of minor importance. To the medical mind the author's style is exceptionally clear and even attractive, but in a few places it seems as though the laity might miss a good deal of the meaning. On the whole, the book will be of service and, at times, of great comfort to anxious young mothers.

Ulceration of the Bladder, Simple, Tuberculous, and Malignant. By E. HURRY FENWICK, F.R.S., Surgeon to the London Hospital, Surgeon and Pathologist to St. Peter's Hospital for Urinary Diseases, Consulting Surgeon to the West Herts Infirmary. Pp. 85. Philadelphia: P. Blakiston's Son & Co., 1900. Price, \$1.75.

The book is divided into three chapters; the first devoted to simple ulceration of the bladder, 31 pages; the second chapter to tuberculous ulceration of the bladder, 46 pages; and the remainder is taken up with malignant ulceration of the bladder. The subject under discussion is an obscure and difficult one and the facts recorded are the result of an extensive and clinical experience, some of the patients having remained under observation for many years. The discussion of the pathology of the conditions under consideration is not as thorough in all cases as seems desirable and perhaps some surgeons will question the advisability of certain suggestions as to treatment. For example, we notice frequent reference to the use of Koch's tuberculin; also the production of paraplegia by inserting a tenatome between the laminae of the vertebrae low down and cutting across the cord to isolate the nerve-supply is suggested. However, the book contains much that is interesting and valuable for those engaged in genitourinary practice.

Rhinology, Laryngology, and Otology, and their Significance in General Medicine. By E. P. FRIEDRICH, M.D., Privat-docent at the University of Leipzig. Authorized translation from the German. Edited by H. Holbrook Curtis, M.D., Consulting Surgeon to the New York Nose and Throat Hospital. Philadelphia and London: W. B. Saunders & Company. 1900.

In the words of the preface, this book "does not pretend to be a special textbook in the ordinary sense, being intended to awaken the interest of both the general practitioner and the specialist in certain matters which appear to me to demand special attention and further elaboration." . . . The bibliographic notes "do not pretend to anything like completeness," yet the author "hopes" he has "cited the most important works, a reference to which will enable the reader to elucidate any doubtful questions that may present themselves." So that at the outset we are informed that only a syllabus of a proper course of research and study in these three great special branches of medicine, is placed in our hands, and after a careful examination of the book we discover that such is really the case. We find no anatomy, physiology nor illustrations of any kind in the entire work of 335 large octavo pages. We have before us practically nothing but a list of symptoms in the nose, throat and ear, which may be observed by the general practitioner in his care of general diseases, but there is no attempt made to mark out a course of treatment for such symptoms and diseases. This work cannot be of use to the medical student. The general practitioner may be interested in it if he has time to follow the line of study suggested by its pages, but it seems to us that the specialist in diseases of the nose, throat and ear is the only one appealed to by the mass of special literature laid before him in this work.

Transactions of the American Surgical Association, Vol. 18. Edited by DE FOREST WILLARD, M.D., Ph.D., Recorder of the Association. Illustrated, pp. 468. Printed for the Association and for sale by Wm. J. Dornan, Philadelphia, 1900.

In a report of the Surgical Association contained in our special number of May 3, will be found quite complete abstracts of the papers presented which are contained in full in this volume. As is usual, the papers presented were of a high scientific value. The symposium on stomach surgery contains a great deal that is of value with regard to this subject and which cannot be found elsewhere. Many of the cases reported were also of special interest, notably those of Elliott and Richardson on removal of tuberculous mesenteric glands and Keen's report on nephrectomy for a large aneurysm of the right renal artery. The special interest which has been taken in celiotomy for peritoneal infection in typhoid fever makes the paper by Warren, reporting 24 cases of this kind, also of particular interest. The volume is well printed, bound and indexed and contains a number of good illustrations.

Ringworm in the Light of Recent Research. Pathology, Treatment, Prophylaxis. By MALCOLM MORRIS, Surgeon to the Skin Department, St. Mary's Hospital. With 22 photomicrographs and 1 colored plate. 8vo, pp. viii, 142. London, Paris, and Melbourne: Cassell & Company, Limited, 1898.

Ringworm is such a common affection that the practitioner needs to be informed concerning its every aspect in order that he may the more successfully cope with it. In the volume before us the question of etiology is carefully gone into and the opinion is expressed that ringworm is of multiple etiology. In the treatment are considered not alone those measures that have proved useful in the author's personal experience, but also those that are recommended by others. The illustrations are excellent and helpful. Four chapters are devoted to the question of etiology, one to that of pathology, two to clinical varieties of the disease, one to ringworm of the beard, one to diagnosis and prognosis, one to treatment, and one to prophylaxis.

L'Année Chirurgicale. Revue Encyclopédique de Chirurgie General et Special. Published under the direction of DR. A. DEPAGE, of the University of Brussels, surgeon to the Brussels Hospital; with the collaboration of many well-known surgeons. Second year, 1899, second fasciculus, 1900. pp. 792. Brussels: Henri Lamartin: Rue du Marché au Bois 20.

In a review of the first fasciculus of this excellent work we have given its general plan. The editors undertake to notice every article which has appeared on surgery during the past year and classify these articles under various headings. First is given a bibliography of the subject under consideration with reference to the place where the article appeared. Then follow brief abstracts of the articles signed by the abstractor. In this volume are taken up the special surgery of the nose, ear and throat, the face, lips and jaw and the thoracic and abdominal organs, including the entire digestive tract. We have formerly expressed our high opinion of the value of this work. It not only enables the surgeon who desires to look up the literature of any subject to find a carefully prepared bibliography, but it gives him a brief abstract of the articles which have appeared. While these abstracts may not perhaps always of themselves be sufficient for those interested in any special subject, they indicate sufficiently the character and value of the articles and in this way may save unnecessary trouble in obtaining some article which is of comparatively little value. We trust that the work will become sufficiently well known and will be enough supported so that the editors and publishers will find it worth their while to continue it in coming years. Such a volume is of particular value now that the *Index Medicus* has been discontinued, which formerly was so useful for those engaged in literary work.

Bacteriology and Surgical Technic for Nurses.

By EMILY M. A. STONEY, Superintendent of the Training School for Nurses, St. Anthony's Hospital, Rock Island, Illinois. Author of "Practical Points in Nursing," etc. Illustrated, pp. 190. Philadelphia: W. B. Saunders & Co., 1900. Price, \$1.25.

This little book contains a brief discussion of bacteriology and the theory of antitoxins. The details of surgical technic and the use of various disinfectants are carefully given; also receipts for the preparation of surgical dressings, lists of instruments for operations, the method of administering anesthesia, preparation of operating rooms, etc. Although the descriptions are briefly given, they seem to be sufficiently complete for the use for which the book is intended, and it will no doubt prove a useful guide for nurses. It may also be of value to surgeons who supervise the preparation of their own dressings and materials for operation.

Tropical Diseases. A Manual of the Diseases of Warm

Climates. By PATRICK MANSON, C.M.G., M.D., S.I.D. (Aberd.). With 114 illustrations and 2 colored plates. Revised and enlarged edition. 8vo, pp. xx, 684. London, Paris, New York, and Melbourne: Cassell & Company, Limited, 1900.

Occasionally one is moved to lament the almost unlimited multiplication of books and to wonder at the destiny of a large number of them. No such emotion, however, arises in connection with the work before us, written, as it is, by a master hand and issued at a time when the entire world is interested, if not involved, in tropical affairs. The disorders considered are neither solely those peculiar to and confined to the tropics nor yet all of those occurring in the tropics, but those occurring only or specially prevalent in warm climates. These differ from those of temperate climates principally in their specific causes, which find under the respective circumstances conditions the more favorable for their existence and conveyance. The text is divided into six sections, namely: Fevers, General Diseases of Undetermined Origin, Abdominal Diseases, Infective Granulations Diseases, Animal Parasites and Associated Diseases, Skin Diseases, and Local Diseases of Uncertain Nature. The article on Malaria is a most comprehensive one, having the first 148 pages devoted to it, and including the most recent knowledge relating to this subject. A similar commendatory statement is equally applicable to the remaining articles. The volume is wholly deserving of praise and will repay careful perusal.

The Operative Surgery of Malignant Disease.

By HENRY T. BUTLIN, F.R.C.S., D.C.L., Surgeon to St. Bartholomew's Hospital; Late Erasmus Wilson Professor of Pathology, and Hunterian Professor of Surgery and Pathology to the Royal College of Surgeons, with the cooperation of several well-known medical men. Second edition, pp. 462. Philadelphia: P. Blakiston's Son & Co., 1900. Price, \$4.50.

Butlin gives as his objects in writing this book the indication of the difficulties of cases, the parts of the body which may be treated by operative means with the best prospects of success and encouragement of the performance of operations in suitable cases at the earliest possible period; the discouragement of the repetition of useless and dangerous operations, and to raise the question of the propriety of the removal of entire organs for the cure of carcinoma of limited extent. The appearance of a second edition of this well-known book and frequent references which we see to it lead us to believe that the author has been successful in his efforts. All parts of the body in which operations for carcinoma are possible come under discussion. The choice of cases, the preparation for operation, the various methods of operating and the probable immediate and permanent results are carefully discussed, and the conclusions seem to us judiciously drawn. The book shows evidence of a most thorough and careful study of the literature of the subject, and of much practical experience. Full and careful references are given to all important papers which have appeared, and the book seems thoroughly up to the times in every particular. In most cases Butlin takes a hopeful view as regards

the results of operations for carcinoma. He believes that about a dozen cases of undoubted gastric carcinoma have been cured by pylorotomy, and that patients who are not cured, are relieved by the operation. In operating on the digestive tract he prefers anastomosis by suture. The results of operation for carcinoma of the rectum are not as good as those for some other parts of the body, but they are not bad; although the first operation is not always successful, several cures have been effected by a second operation. He believes that in spite of the disagreeable sequels which sometimes follow, it may be fairly said that the patient's comfort is increased and his life prolonged by operation. In operation for removal of carcinoma of the breast, Halsted's method is preferred. Butlin states that he has used this as his routine method of operation since 1895. The percentage of cases in which the patient has remained free of disease for 3 years or over during the 5 years in which he has used this method is nearly 70%. But Butlin has no hope that we shall for the present permanently succeed in attaining such excellent results, as there is no doubt that this series was a very fortunate one, and he believes that his next series of cases will not yield equally good results. In all operations for malignant disease great stress is laid upon the importance of early operation. The book is worth careful reading, and every surgeon will certainly want to own a copy.

A Practical Treatise on Fractures and Dislocations.

By LEWIS A. STIMSON, B.A., M.D., Professor of Surgery in Cornell University Medical College, New York City; Surgeon to the New York and Hudson Street Hospitals; Corresponding Member of the Société de Chirurgie of Paris. Third edition, revised and enlarged. In one handsome octavo volume of 842 pages, with 336 engravings and 32 full-page plates. New York and Philadelphia: Lea Bros. & Co., 1900. Cloth, \$5.00, net; leather, \$6.00, net; half morocco, \$6.50, net.

Stimson's book on fractures and dislocations has long been regarded as the standard text on this subject in the English language. The book is too well known to need any extended description of its general plan and its teachings are too sound to permit very much criticism. This third edition has been thoroughly revised and seems to be quite abreast of the times. The section on fractures of the spine, including a discussion of hematomyelia, the reference to the operative treatment of dislocations, and the teachings with regard to many other subjects give evidence of this. The tone of the book is conservative and safe. For example, we find the following with regard to the treatment of fractures of the patella: "I believe certain methods, when surrounded by every precaution, may be employed with the assurance of success that justifies resort to them, and while I habitually use them yet I have never taught them as routine practice. But, on the contrary, I strongly advise against their use except by those who can bring to them not merely experience in operating, but also the habit of taking surgical precautions and the aid of trained assistants who have the same habits, who are practising those precautions daily; in short, the personnel of an active surgical hospital service. The general practitioner, even the occasional surgeon, is not only fully justified in using nonoperative methods (in treating fractures of the patella), but ought to do so, and he can feel assured that the method at his command justify the expectation of a satisfactory, even if not perfect, result." The method of reducing dislocations by continuous traction of a weight seems simple, safe, and deserving of general adoption. This original method has been published by Stimson during the past year. This edition of the book contains many new and valuable cuts and particularly some very good x-ray cuts illustrating the conditions found in various fractures and dislocations. There are still some rather old and complicated methods illustrated and described which we think might with advantage have been omitted; for example, Middeldorpf's triangle for fracture of the humerus and the old-fashioned side traction splint. The usefulness of massage in the treatment of fractures and dislocations is perhaps not sufficiently emphasized, and the author seems to be somewhat more conservative than most modern surgeons in the operative treatment of fractures. However, on the whole, the book is very complete, its teachings thoroughly modern, and it will no doubt continue to be the standard book of reference on this subject for some time to come.

Correspondence.

ETIOLOGY OF YELLOW FEVER.

By WALTER REED, M.D.,

of Columbia Barracks, Quemados, Cuba.

Surgeon U. S. Army.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

REFERRING to our paper on "The Etiology of Yellow Fever—a Preliminary Note"—which was published in the issue of your journal for October 27, 1900, we regret very much that, in quoting from memory, we have unintentionally misconstrued Veazie's results in the epidemic which prevailed in New Orleans during the summer and fall of 1899. We said, if we remember correctly, Veazie, of New Orleans, has recently reported that during the epidemic of 1899 in New Orleans, a pure culture of *B. icteroides* was not isolated in any case of yellow fever.

Since the appearance of our Preliminary note, we have, through the courtesy of Dr. Veazie, received a reprint of his paper (Estivoautumnal Fever in New Orleans, Summer and Autumn, 1899, *N. Y. Med. Journal*, May 19 and June 2 and 9, 1900), from which we quote: "I know of no instance as yet when *Bacillus icteroides* has been found in the bodies, dead or alive, of those afflicted with the prevailing fever this year (1899); that is, no true cultures have been developed, although repeated trials were made by different bacteriologists."

Dr. Veazie then proceeds to show, both by blood-examinations and by postmortem appearances, that the prevailing disease was malaria and not yellow fever. In this connection it is but fair to state that Dr. Veazie, taking cultures from the ear-lobe on the third day of the disease, during the prevalence of the epidemic of yellow fever in New Orleans in 1898, claims to have obtained *B. icteroides* in 19 cases out of 23. His failure to obtain this bacillus in 1899 was, therefore, one of the reasons which led him to conclude that the much disputed epidemic of that year was malarial in character.

POTASSIUM IODID IN SATURATED SOLUTION. A STUDY OF THE DROP.

By J. HENRY SCHROEDER,

United States Chemist,

of Cincinnati, O.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

UPON superficial consideration of this subject it would not appear that it embodied much food for thought. The drop has, of necessity, remained as one of the popular means of measuring medicine, and, erroneously, a drop is usually considered to be equal to a minim, at least for all practical purposes. It has long ago been demonstrated, however, that this may be the case with distilled water under certain conditions, but does not hold good for the majority of liquids.¹ The size of a drop depends upon the orifice from which the liquid in question may be dropped, from the surface over which the drop must flow before it drops, and also upon the consistency and character of the liquid. This will be clearly

demonstrated in a later part of this paper. I believe that potassium iodid is practically the only salt which is prescribed and dispensed in saturated solution. This is because of its extreme solubility, one part being completely soluble in 0.75 parts of water and 15° C. It is my experience, and a special inquiry has developed the fact, that in most cases the physician who thus administers potassium iodid expects that the patient shall receive one grain of the salt with each drop of the solution, or practically that amount. The basis for this accepted theory may, perhaps, be found in the belief that one fluid ounce of a saturated solution of potassium iodid contains 480 grains of the salt, and that the 480 minims of the fluid ounce are equal to 480 "drops." Any variance in the quantity of the salt contained in one "drop" of the solution must necessarily bring about a variance in the result of the treatment, whether the doses administered be small or large. Only recently an instance has come to my notice, where a physician administered 300 drops of the saturated solution per day, with the expectation that the patient received a total of 300 grains of potassium iodid during that period. The result of the treatment was not at all in accordance with this dose supposedly administered.

This method of administering potassium iodid is probably not of recent origin, yet the theory that each "drop" of its saturated solution contains *practically* one grain of the salt, seems not to have ever been doubted or investigated; at least, records of such a study are not among the treasures of pharmaceutical and medical literature that I have at my disposal. Perhaps the subject seems insignificant at first, but the results of my investigation may have justified the study.

The Saturated Solution.—24.1835 grams (372.4 grains) of potassium iodid was dissolved in the smallest possible quantity of distilled water, at ordinary temperature, and this finished, saturated solution measured 26 cc. (or 7.033 fluid drams = 421 minims) or, in order to contrast more prominently, 422 minims contained 372.4 grains KI. This proves that one *minim* of the solution does *not* contain one grain of the salt, but less. The following experiments prove that:

1. One "drop" is not equal to one minim of the solution.
2. The variance of the size of a drop of solution, according to whether the solution is dropped from a pipet (ordinary medicine dropper), from a glass tube, or from the lip of a prescription bottle. (It will be noticed that only such dropping mediums were selected as are used by patients.)
3. The exact quantity of potassium iodid contained in the respective "drop."

The figures may be better contrasted when arranged in tabular form:

3.7 CC. (OR 1 FLUID DRAM) OF POTASSIUM IODID SATURATED SOLUTION.

DROPPED FROM.	NUMBER OF DROPS.	GRAINS KI. IN EACH DROP.
Pipet, orifice 2 mm., walls thin, held <i>vertically</i> .	113	0.46
The same, <i>inclined</i>	78	0.68
Glass tube, orifice 6 mm.	58	0.91
Lip of prescription-bottle (6 mm.)	124	0.43

3.7 cc. (1 fluid dram) = 60 minims. Each minim contains 0.88 grains.

From the above figures it will be seen that it is entirely impossible to administer potassium iodid with any exactness of dosage when dispensed in the form of a saturated solution.

LIGAMENTOPAXIS.

By CARL BECK, M.D.,

of New York City.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

FULLY appreciating the fact that the *Centralblatt für Chirurgie* (August 21, 1897), in which I first published my method of suspending the uterus on the round ligaments, may have been inaccessible to Dr. D. Tod Gilliam, I must differ from the position which Dr. Gilliam takes in your issue of November 3, where he writes: "The only thing in common is the inclusion of the round ligament in the abdominal wall. If Dr. Beck can establish priority for this very important feature of the operation, he is entitled to credit for it." The interrogative "if" seems, to say the least, odd, in view of the more than ample proofs of my priority, as shown in this journal. Dr. Gilliam has apparently not looked up the dates thoroughly, and has only read the article which described the latest modification of my original operation (*American Journal of Obstetrics*, Vol. xlii, No. 3, 1900). Therefore, if he intends to convey that this last modification of mine differs from the one which he describes as his own, he is perfectly right, because what he published was not my modification, but my original operation (published more than three years ago). I certainly am grateful to Dr. Gilliam for further modifying my method of ligamentopaxis, which does not, however, exclude my claims for my original work.

CALENTURA OR FEVER?

By EUGENE STADELMAN, M.D.,

of Descurridora, Dgo., Mex.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I HAVE read with great interest the article "Concerning Calentura" that appeared in the issue of October 13. I fail to understand why Dr. Foxworthy limits the term "Calentura" to a particular form of fever that occurs at a particular time of the year. In Mexico the name is applied to any form of fever, not as a name for the disease, but to designate the presence of fever. Among the better classes, the more expressive word "fiebre" is used in the same sense. Calentura literally means a "heating up," and when used in the plural, "Las Calenturas," it signifies some form of malaria accompanied by chills.

ANALGESIA IN OBSTETRICS PRODUCED BY MEANS OF CARBONIC-ACID GAS DOUCHE.

By A. ROSE, M.D.,

of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

TO your editorial "Patriotism and the Zeitgeist in Medicine" I wish to offer an illustration how an American discovery is neglected.

In the *Medical and Surgical Reporter*, Philadelphia, February 18, 1871, appeared an article "On the induction of local anesthesia in labor by the use of carbonic-acid gas," by Theodore A. Demme, M.D., of Philadelphia. In this paper the author reports the following three cases:

CASE 1.—In December of last year, I received an urgent call to wait upon a lady who, it was stated, was in labor, and had been in convulsions for several hours. Upon arriving at the house I was informed by the midwife having the patient in charge that she had been in labor over 20 hours; the

bag of waters had ruptured almost at the commencement of labor and, although the pains were frequent and excessively severe, the mouth of the womb had scarcely dilated any during the last 10 hours, and that she was about to request the attendance of a physician when convulsions came on. I recognized at a glance that I had before me a terrible case of eclampsia or puerperal convulsions. The patient was lying in a totally unconscious condition, and at short intervals would be seized by a spasm, convulsing every muscle of the body, jerking violently the head to one side, and at the same time bending the body backward as if the head and heels were to approach one another; the features were distorted; the throat and face tumid and purple, and the eyes rolled up in the orbits—it seemed as if they would start from their sockets. Upon examination I found the os uteri dilated to about the size of a half-dollar piece, and extremely hard and rigid. This rigidity continued not only during the pain, but in the intervals; there was, in fact, a constant spasmodic rigidity. The commencement of a pain and the onset of a convulsion were almost simultaneous, it appearing as if the pressure of the child's head upon the irritable and sensitive os was the direct cause of the eclampsia.

The indication was undoubtedly to dilate the os and deliver, but every attempt at forcible dilation aggravated the symptoms, and I therefore bled the patient freely from the arm, in the hope of promoting the relaxation of the spasmodically contracted muscles; but although I controlled the arterial circulation and reduced the volume and frequency of the pulse, I found that even excessive bloodletting had no effect upon the rigid os. The idea then flashed upon my mind of using the carbonic-acid gas. After a delay of 15 minutes consumed in procuring the apparatus, I applied the gas to the uterus. When the douche had been continued for about 5 minutes, it was evident that some change had been produced, for the patient remained quiet, and no convulsive movement took place. A few minutes more, and the anxious family, startled by the great change that had occurred in the behavior of the patient, imagined that she was dying, and only the regular beating of the pulse assured me that such was not the case. Fifteen minutes after the application of the gas there was a slight tremor of the body, when I again carried the gas-tube into the vagina, and in so doing examined the womb, and to my astonishment and great satisfaction found the os not only no longer rigid, but fully dilated, and the head about passing the superior strait. I immediately applied the forceps and delivered. The patient, after remaining unconscious for several hours, suddenly awoke as if from a sleep, and asked for a glass of water. Convalescence proceeded favorably.

In this case we had a revelation of the power of carbonic-acid gas as an anesthetic agent over an extremely sensitive and irritable os uteri, controlling rigidity without any apparent interference with the contractile or expulsive efforts of the uterus.

CASE 2.—January 3, 1871, Mrs. D., primipara. When called to the patient, labor had been in progress about two hours. The pains were excessively severe and frequent. The patient was nervous and extremely irritable, allowing neither herself nor those surrounding her any rest. Per vaginam examination gave little hope of speedy termination. The os uteri was dilated about one-half, the edges dry, hot and cold-like. After waiting 30 minutes and perceiving little or no progress, I determined to use the carbonic-acid douche. The patient having been assured that she would receive relief, offered no opposition to the application. After the gas had been allowed to act upon the mucous membranes for 5 minutes the entire demeanor of the patient was changed. The demonstrations of suffering, impatience and irritability were succeeded by a calm so complete that it seemed as if the labor had been suddenly arrested. The douche was repeated in 10 minutes, and the observation made that whilst the patient asserted that she felt no pain, the bag of waters was pressing firmly upon the now rapidly yielding os. In exactly 15 minutes from the termination of the first douche, the dilation being almost complete, I ruptured the bag of waters and almost immediately perceived the head entering the pelvis. Five minutes after the escape of the waters the third application of the gas was made. The head had now entered the pelvic cavity and was pressing upon the perineum.

The patient at this time, in answer to the questions, stated "that she felt no pain," "did not feel the head at all." In fact, did not believe she was to have a child. Very shortly after, however, the relief from suffering ceased, and the passage of the inferior strait was accomplished with all the usual symptoms of pain. The further progress of the case presented no particular features.

CASE 3.—January 4, 1871, Mrs. D., aged 37; second confinement; 13 years elapsing since the birth of the first child. When engaged to attend this lady I anticipated a difficult labor, in consequence of the great length of time that had passed since the birth of the first child. Such was, however, not the case. Being called to the patient at 9 A.M., I was enabled to leave the house at 11.15 A.M., the mother lying comfortably in bed and the nurse dressing the newborn babe.

In this case I made four applications of the gas, at ten minute intervals, during the first (or dilating) stage of the labor, with the effect of greatly ameliorating, but not entirely relieving the sufferings, the patient complaining from the very commencement of labor of pain in the back and of cramps in the limbs.

CASE 4.—January 21, 1871; Mrs. E., primipara. The gas douche applied every ten minutes, with the effect of relieving the pain in so marked a manner that it was with difficulty that I could convince the mother and nurse that I had not stopped the labor. Indeed, it was only when the sufferings became intensified, as the head pressed on the perineum, that they again had faith. In this case the gas injection was applied four times, at intervals of ten minutes.

Dr. Demmé in conclusion says: "I would urge upon my medical brethren to give this agent a fair trial, and to report their experience. The number of cases in which I have used the gas is too limited to form a proper estimate of its value. Nevertheless, in cases of rigid, unyielding, irritable os uteri, I regard it as a boon, relieving the suffering and expediting the labor."

The paper of Demmé in which these cases are given was referred to in several of my publications on carbonic-acid treatment. I mentioned Demmé's discovery before the Obstetrical Section of the New York Academy of Medicine, at the occasion when I reported a case of my own in which I had succeeded to produce anesthesia during labor by means of the carbonic-acid gas douche; but it seems indeed, a method discovered by an American physician has to be discovered or at least ascribed to some European physician before the profession here will take the pains to notice it or give it a trial.

As far as my knowledge goes—and I have read every book and paper on carbonic-acid treatment which I could find in the library of the New York Academy of Medicine and the Surgeon-General's library in Washington—Demmé was the first who wrote on this method of anesthesia in labor, and I have not seen a single notice in any journal about his paper; certain it is that it is not mentioned in any of the textbooks on obstetrics that I have examined.

Fulminating Appendicitis.—C. A. Wheaton (*St. Paul Medical Journal*, November, 1900) says that he has noticed in nearly all of his cases the occurrence of vasomotor paralysis which brings about a cyanosis of the trunk, particularly of the abdominal region. He regards this as a symptom of general abdominal suppuration. He has not seen the sign mentioned in any textbook. Every case of appendicitis should be considered surgical, because the surgeon's training specially qualifies him to best interpret the meaning of the symptoms encountered. Every case of so-called "fulminating appendicitis" should be operated upon as soon as its distinctive characteristics are known. High temperature and high pulse associated with local pain and rigidity are strong presumptive evidences of malignancy in the attack, and if associated with the vasomotor disturbances before referred to, are practically proof of perforation. [G.C.C.H.]

Society Report.

SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Thirteenth Annual Meeting, Held in Atlanta, Georgia
November 13, 14, and 15, 1900.

THE Association met in the ballroom of the Kimball Hotel, under the presidency of Dr. A. M. Cartledge, of Louisville, Kentucky. Governor Candler, of Georgia, delivered the address of welcome, which was responded to by President Cartledge.

Medullary Narcosis.—DR. W. L. RODMAN, of Philadelphia, read a paper in which he discussed the points of most practical value in connection with this method of anesthesia. Will it displace ether and chloroform in operations below the diaphragm? No one, however optimistic he may be concerning this new method of producing analgesia, will think of abandoning ether and chloroform. These trusted agents will continue to enjoy the confidence of the profession, and the Corning-Bier method will be held in reserve for certain cases where there is seemingly a clear contraindication to chloroform or ether. Medullary narcosis should be given subjects suffering from bronchial, pulmonary, and renal diseases; to patients affected with fatty or dilated heart, and cardiac diseases in general. It may also be given to old people in whom the shock of general anesthesia is oftentimes great, and from its action in one case the author believes it to be safer than chloroform or ether in drunkards. The place where the spinal canal is entered is of some importance. Tuffier, Murphy, Matas, and others, who have had the largest experience with the method, prefer the fourth lumbar space. In the opinion of the author any of the lumbar spaces can be punctured with safety. The fifth interspace between the last lumbar and the first sacral vertebrae is in some respects the easiest route. The author considered the primary dangers of simple puncture without injection. It has not been shown that secondary changes, either inflammatory or degenerative, have taken place in either membranes or cord leading to chronic disease. Theoretically, one might fear some form of sclerosis. Simple puncture of the spinal cord, if aseptically done, is unlikely to be followed by serious changes in the cord or its membranes. If to simple puncture is added the injection of some chemical substance by which anesthesia is produced, a new element of danger is undoubtedly incurred. Therefore, the choice of a local anesthetic becomes of paramount importance. Cocain is difficult to sterilize, as it cannot be boiled without impairing its anesthetic properties. Raised to a temperature above 180° F., it is decomposed into ecgonin, and becomes comparatively inert. Some have found it practical to boil cocain, and then introduce it into the spinal canal without impairing its anesthetic properties. By raising it to a temperature of 180° F., and repeating this twice, thrice, even six times, as recommended by Tuffier, it should be sterile, and therefore safe, and yet a dose of 30 minims of a 2% solution of cocain is too large in the judgment of the essayist. He recommended half of this amount. A small dose of a 2% solution is better than a larger one in greater dilution. He has reduced the number of minims of a 2% solution each time he has practised the method, and thus far he has not failed to obtain complete analgesia. In his first case he injected 18 minims; in the second, 15 minims, and in a third, 13 minims, and hopes still further to reduce the amount to 10 minims. We should aim to get complete anesthesia with the smallest amount of the drug. The primary and secondary effects of the injection of cocain into the spinal canal are those of simple puncture exaggerated. Shock is increased, headache, restlessness, delirium, and other symptoms are necessarily more pronounced. The speaker referred to the method of injection, the length, size, shape, and composition of the needle. He recommended an irido-platinum needle. He described the technic of the method, which was similar in many respects to that outlined by Tuffier and others. He blindfolds the patient and fills the ears with cotton to avoid psychic pain.

DR. LEWIS S. McMurtry, of Louisville, predicted that medullary narcosis would not take the place of the estab-

lished methods of anesthesia, and said that its field of usefulness would be restricted to the class of cases outlined by the essayist.

DR. WILLIS G. MACDONALD, of Albany, mentioned the case of a man of 42, who had suffered from **hemorrhoids and fissure of the rectum**. The patient had always been a hard drinker. Granular and hyalin casts were found in the urine, also a small amount of albumin. Patient likewise had a fatty, dilated heart. He injected 18 minims of a 2% solution of cocain in the subdural space, and when he was about to begin the operation the patient became cyanotic; a profuse, cold perspiration began, so that it became necessary to give the patient $\frac{1}{16}$ grain of strychnia, $\frac{1}{8}$ grain of nitroglycerin, when the respirations ran up to 60 or 80. No pulse was discernible at the wrist. The pupils were dilated; patient became unconscious. More than 2 hours elapsed before the speaker felt safe as to the condition of his patient. The man suffered severely from headache and projectile vomiting during the entire afternoon, and had two or three involuntary bowel movements. Two days later Dr. MacDonald administered nitrous oxid and ether and operated on the hemorrhoids. Patient recovered. During the summer, while on a visit to Europe, he saw a similar experience in the practice of Professor Kocher.

DR. A. M. CARTLEDGE, of Louisville, said his experience was limited to 8 cases in which he had used this method of anesthesia, the results being satisfactory. In two patients severe headache followed its use, which soon disappeared. Analgesia was complete in all cases. In one case he operated for the removal of pus tubes; in a second he removed an enormous fibroid tumor of the uterus; and in a third a large intraligamentous cyst. Some of the patients came off the table in much better condition than if chloroform or ether had been employed.

DR. E. P. MALLETT, of New York City, detailed a case of retroverted adherent uterus in the practice of Dr. Grandin, for which an abdominal section was made. At first, much difficulty was experienced in finding the subdural space or medullary canal, so that the patient complained of intense pain. It was finally found, cerebrospinal fluid escaped, and cocain was injected, the analgesia being apparently complete in 18 minutes. So much pain was experienced while the operator was making the incision that it became necessary to administer a few whiffs of chloroform to complete the operation. He also detailed another case of posterior vaginal section for pelvic abscess. In this case the needle was introduced more quickly and with better success; but slight vomiting as well as other symptoms occurred. The subsequent course of both patients was uneventful.

DR. BEVERLY MACONIGLE, of San Francisco, spoke of 2 cases which he saw in the practice of Dr. Barbat, of San Francisco, in which medullary narcosis was used successfully. However, he was told by both patients afterwards, and by Dr. Barbat, that they suffered a good deal from vomiting after they had been taken to their rooms, but subsequently recovered without any marked incidents.

DR. SENECA D. POWELL, of New York City, did not think the time is ripe for this method to be presented to the profession at large. The result should be worked out by experienced hands. He pointed out the dangers of cocain, referred to the susceptibility of some patients to the drug, and cited 2 cases that had occurred in his own practice in which he had used cocain, saying that both patients came very near dying from its effects.

DR. RODMAN said he had used medullary narcosis on a man 45 years of age, who had a bursa in the popliteal space, with marked kidney trouble. The result was satisfactory in every respect. The next case was one of advanced kidney trouble in which he did a suprapubic cystotomy. Result, satisfactory. He would use medullary narcosis in those cases in which there are positive contraindications to ether or chloroform. The surgeon should always obtain the consent of the patient before using the method on account of any medicolegal complications that might subsequently arise.

The Removal of Pelvic Inflammatory Masses by the Abdomen After Bisection of the Uterus.—DR. HOWARD A. KELLY, of Baltimore, has recently pointed out the great advantages which accrue from bisection of the myomatous uterus in an abdominal enucleation in certain complicated cases. In previous contributions he had described his method of enucleation by a continuous transverse

incision from left to right, or from right to left. He now called attention to the great value of a somewhat similar procedure in certain cases of pelvic inflammatory diseases. The steps of the operation are these: If the uterus is buried out of view, the bladder is first separated from the rectum and the fundus found. Then, if there are any large abscesses, adherent cysts, or hematomata, they are evacuated by aspiration, or by puncture. The rest of the abdominal cavity is then well packed off from the pelvis. The right and left cornua uteri are each seized by a pair of stout museau forceps and lifted up, the uterus is now incised in the median line in an anteroposterior direction, and as the uterus is bisected, its cornua are pulled up and drawn apart. With a third pair of forceps the uterus is grasped on one side of its cut surface, as far down in the angle as possible, including both anterior and posterior walls. The museau forceps of the same size is then released and used for grasping the corresponding point on the opposite cut surface, when the remaining museau forceps is removed. In this way two forceps are in constant use at the lowest point. He commonly applies them three or four times in all. As the uterus is pulled up and the halves become everted, it is bisected further down into the cervix. If the operator prefers to do a panhysterectomy, the bisection is carried all the way down into the vagina. The uterine canal must be followed in the bisection, if necessary, using a grooved director to keep it in view. The museau forceps are now made to grasp the uterus well down in the cervical portion, if it is to be a supravaginal amputation, and the cervix is bisected on one side. As soon as it is divided and the uterine and vaginal ends begin to pull apart, the under surface of the uterine end is caught with a pair of forceps and pulled up, and the uterine vessels which can now be plainly seen are clamped or tied. As the uterus is pulled still further up, the round ligament is exposed and clamped; then, finally, a clamp is applied between the cornu of the bisected uterus and the tuboovarian mass, and one-half of the uterus is removed. The opposite half of the uterus is also taken away in the same manner. The pelvis now contains nothing but rectum and bladder, with right and left tuboovarian masses plastered to the sides of the pelvis and the broad ligaments, affording abundant room for investigation of their attachments, as well as for deliberate and skillful dissection. The wide exposure of the cellular area over the inferior median and anterior surfaces of the masses offers the best possible avenue for beginning their detachment and enucleation. The operator will sometimes find on completing the bisection of the uterus that he can just as well take out each tube and ovary together with its corresponding half of the uterus, reserving for the still more difficult cases, or for a most difficult side, the separate enucleation of the tube and ovary after removal of the uterus. The operation just described is not recommended to a beginner in surgery. The surgeon who undertakes it must be calm, deliberate, and must bear in mind at each step the anatomic relations of the structures. He has had abundant opportunity to demonstrate the practical value of this method of treatment in his clinic this year. The advantages of a bisection and enucleation of the uterus as a preliminary to a complete enucleation of uterine tubes and ovaries for pelvic inflammatory and other diseases by the abdominal route were briefly recapitulated: 1. Additional space for handling adherent adnexas, afforded by the removal of the uterus. 2. Great increase in facility for dealing with intestinal complications. 3. Better access by new avenues from below and in front to adherent lateral structures. 4. Elevation of structures to or above pelvic brim, or even out into the abdomen, bringing them within easy reach of manipulation and dissection. 5. Some advantage in approaching both uterine vessels by cutting from cervix out towards the broad ligament, as is secured in approaching one of them in the continuous transverse incision. In general, the time of the operation is shortened; its steps are conducted with greater precision; surrounding structures are far less liable to be injured. In this way, there are fewer troubles and sequelae, and the mortality is lessened.

Vesicovaginal Fistula.—DR. M. C. MCGANNON, of Nashville, Tenn., has applied the principle of Mackenrodt in 6 cases, during the last two years, with primary union and complete closure of the fistula in every case. The technic in each case was the same, and this the author outlined at considerable length.

Report of a Case of Osteofibroma of the Uterus.—DR. GEORGE BEN JOHNSTON, of Richmond, Va., narrated this case. He operated upon the patient April 10, 1900. Bimanual examination, made before the operation, revealed two tumors, one a large fibromyoma, situated posteriorly and to the right of the uterus; the other a small tumor, anterior and to the left. Complete hysterectomy was performed. The smaller tumor was found to be intramural and situated at the junction of the body and the neck. On liberation the microscopic examination showed a tumor about the size of a small orange, and of firm consistence. Held between the thumb and fingers, it gave the sensation that is produced by pressing a hard-boiled egg, the shell of which has been broken. Plates, apparently of bone, surrounded the surface, and on opening it a substance resembling medullary tissue was found. This was unfortunately lost, so that no subsequent histologic study of it could be made. Attached to the lower part of the osseous tumor was a small fleshy mass, which contained a body about an inch in length resembling a heart in shape. On opening the uterus a recent placental site was found near the uterine opening of the right fallopian tube.

Appendicitis in the Female.—DR. F. W. McRAE, of Atlanta, Georgia, quoted eminent authorities "to show the divergence of opinion as to the relative frequency of the disease in the male and in the female. In practically all of the cases that had come under his observation in females, mistakes in diagnosis had been made either by himself or by the attending physician. Almost all of the attacks had occurred at or about the menstrual term, and most of them had been diagnosed "inflammation of the tube or ovary." In two cases of his own series the appendix and the right tube and ovary were involved; in two others the appendicular trouble was complicated with diseased kidneys. Two patients suffered with recurrent appendicitis, and attacks of renal colic before or after operation for the removal of their appendices. He had records of 49 cases of appendicitis seen within the last 16 months, 29 of them being males, and 20 females. During this period he had operated on 17 males, and 14 females.

DR. GEORGE BEN JOHNSTON expressed the conviction that chronic appendicitis is quite as frequent in the female as in the male. He believes, however, we see fewer cases of the fulminating form of the disease in the female than in the male. He has observed numerous cases of chronic appendicitis associated with movable kidney in females, and it is sometimes difficult to determine which is the cause of distress for which the patient consults a surgeon, the diseased appendix or movable kidney, or both. The coexistence of the two conditions is so frequent in his practice that oftentimes he keeps patients under observation for days, perhaps weeks, to determine which is the more distressing condition.

Drainage in Abdominal Surgery.—DR. J. W. LONG, of Salisbury, North Carolina, said that the chief purposes for which drainage is employed are to drain away existing septic material; to afford an exit for the sepsis when the operator fears he has possibly infected his patient; to provoke adhesions and thereby wall off weak spots from the remainder of the abdominal contents; to keep the peritoneal cavity free of blood and other fluids; to allow of a more certain knowledge of the conditions present in the abdomen. Gauze drains are sometimes employed as tampons to control hemorrhage. These features of drainage were discussed in the order given. After referring to the work of Wegner, in 1877, and that of Muscatello, in 1895, and others, regarding the histology and physiology of the peritoneum, the author passed on to the consideration of objections to drainage, and these were enumerated as follows: 1. Drainage is deceptive. 2. Cases not drained do better. 3. Drainage is neither scientific nor workmanlike. The last statement was made with an apology and due deference to those distinguished gentlemen who drain most of their cases.

Atresia of the Vagina.—DR. GEORGE H. NOBLE, of Atlanta, described a flap operation for the relief of this condition, saying that he had operated successfully in several cases by the plan he had outlined.

Recent Technical Improvements in the Surgery of the Stomach for Carcinoma.—DR. WILLIS G. MACDONALD, of Albany, N. Y., said that any one, or a combination of symptoms, is a sufficient indication for operation: 1. A chronic gastritis which is progressive in character under

proper dietetic, medicinal, and physical treatment. 2. A loss of gastric motility. 3. Progressive diminution of gastric peristalsis. 4. A diminution of free hydrochloric acid, progressive in character. 5. Emaciation of the patient under forced diet. 6. Reduction of the hemoglobin in the blood, progressive to 65%, or under, and a moderate leukocytosis. The widest extirpation is demanded in carcinoma of the stomach. All surgery for carcinoma involves the removal, as far as is compatible with adjacent anatomical structures, of lymph nodes. In a complete pylorotomy, it is desirable to remove the lymphatics along both curvatures of the stomach as well as those lying behind the pylorus. As a rule, the duodenum is not extensively involved in pyloric carcinoma, although a few observers have found infiltration of Brunner's glands in the upper portion of the duodenum. There is little justification for the total extirpation of the stomach in the majority of cases, and the probability of cure will not be greater than surgical resection. The old rule on cutting 1 cm. beyond all evidences of carcinomatous infiltration is not wide enough. Personally, the author feels that the line of excision in the stomach should be at least 3 cm. from the border of the last palpable infiltration, and in the duodenum at least 2 cm. from the most dependent portion of the growth. The speaker's earlier gastroenterostomies were done by the Wolfier method of attaching the jejunum and the anterior wall of the stomach. It appears to him that the two fatal cases in which he applied that method were due to regurgitation of bile into the stomach and persistent vomiting following operation. Some two years ago he began employing von Hacker's method of attaching the jejunum to the posterior gastric wall with a reanastomosis between the duodenum and the jejunum. The results of this method of operation have been most satisfactory. During the past year he has employed it 8 times, with 7 recoveries. For the most part, the anastomosis between the jejunum and stomach has been made by the suture method, although a number of surgeons have been quite as successful in the employment of the Murphy button. For the secondary anastomosis the author has uniformly used a Murphy button of moderate size. The anastomosis by this method requires very little time for its performance and can be readily completed in five minutes. When an operation has been carried out by this method to its completion, the following advantages were claimed for it: 1. Freedom from contamination of the wound by stomach contents. 2. Accessibility of the neighboring lymphatic nodes for extirpation. 3. No subsequent danger from suture perforation. 4. Freedom from loss of blood. 5. The great saving of time required for the operation.

Menstrual Condition of the Average Girl in Average Health.—DR. GEORGE J. ENGELMANN, of Boston, presented an interesting statistical paper on this subject, and the facts presented by him were culled from the records of 4,873 cases from high and normal schools, colleges, and department stores, girls between 15 and 26, the majority between 18 and 22, in somewhat better than average health, in good health, and in numbers sufficient to admit of positive deductions as to what may be termed normal or average menstruation. In brief, the menstrual period proper is intensified by the increase of all vital energies, followed by a depression which appears with the coming of the flow. Under ideal conditions, and in perfect health, the physiologic status is such that this epoch, preceded by a day or two of heightened activity, is marked by a moderate lassitude, mental and physical, the flow persisting for from 4 to 5 days, and recurring at regular intervals of about 28 days. It is a period of heightened susceptibility that quickly records any variation from the normal; excitement or exertion, or fatigue, mental or physical, are promptly reflected by variation in the function, and in our everyday life such disturbing elements constantly occur, so that conditions actually existing vary greatly from this ideal. The average period of the average girl in average health presents very different features: Regularity in 50% of the cases only; recurrence every 28 days in 30%; varying most frequently from 26 to 42 days, 45%, being over 23. The duration varies from 2 to 7 days, average 4.6; from 66% to 70% suffer more or less, the number of sufferers varying according to age and nature of occupation, between 30% and 90%. Lessened ability for exertion, mental or physical, is admitted by 60%. Some few are habitually incapacitated from work, and 30% occasionally. The function of the condition of the girl in good health, under mod-

ern conditions of life, is by no means an ideal one in the judgment of the essayist, and in fact the functional health of the American girl, the coming mother of American men, is far from what it should be by right of inheritance and surroundings. This fact physicians must recognize, and upon them and educators devolves the duty of study and correction of the evil.

Operation for the Treatment of Marked Pro-lapse of the Rectum in Women.—DR. J. WESLEY BOVEE, of Washington, D. C., described an operation for the relief of this condition by fixing the uterus to the abdominal wall, then drawing up the rectum and fixing it to the posterior wall of the uterus.

Carbolic Acid in Surgery.—DR. SENECA D. POWELL, of New York City, read this paper. In 1894 he first became convinced that he could control the action of carbolic acid under all circumstances. At that time he used it in its full strength of 95% in an abscess-cavity upon a patient suffering from suppurative appendicitis. Since then he has extended its use to all cases where he has had to fight disease due to microbic infection, and he is now prepared to assert its safety and reliability, when properly brought in contact with an infected surface. He bases his statements on the results of treatment of hundreds of cases which have come to his clinic at the Post-Graduate Hospital, New York. The essayist quoted Phelps, of New York, as saying that to him (Dr. Powell) the profession is indebted for one of the most useful discoveries ever made in surgery, namely, the antiseptic effect of alcohol in carbolic acid. The speaker has used carbolic acid for years in the treatment of infections and bone diseases in various parts of the body. He recommends its use likewise for erysipelas and abscesses. During the past six years he has treated every phase of microbic disease with this agent, and as early as 1894 hip joint cases were treated by him with pure carbolic acid and with a large glass drainage-tube. Abscesses, wherever located, can be speedily treated by the injection of, or swabbing with, pure carbolic acid. The size of the abscess, or the amount of surface covered, is not a factor. Only thorough drainage and complete removal of the pyogenic membrane need be considered.

Early Excision for Dislocations Not Reducible by Manipulation.—DR. WILLIS F. WESTMORELAND, of Atlanta, reported two cases; the first was an arthrotony, with excision of the head of the humerus, for old dislocation of the shoulder-joint, the second a shoulder dislocation received while boxing.

A Plea for the Better Appreciation of the Limitations of Operative Work.—This was the title of the president's address, delivered by DR. A. M. CARTLEDGE, of Louisville. Every surgeon must be his own arbiter in deciding questions, and the judgment he displays will depend upon his professional learning and wisdom. Methods of surgical diagnosis have undergone striking modifications within the past decade and have influenced operative work. The older surgeon made his diagnosis of abdominal and pelvic lesions slowly; his skill at that time consisting largely of a delicate sense of touch, trained eye to detect asymmetry, keen ears to differentiate sounds elicited by percussion, and methodical investigation of all symptoms both subjective and objective. The result was his diagnosis having been made, he next carefully, and with abundant time before him, considered the advisability of operative intervention. It is as much a part of the knowledge of surgery to know its limitations, or what it cannot do, as to be justly proud and ready to perform that which it has very good reasons to believe will be productive of relief, and cure to the thousands of unfortunates who seek its aid. From every standpoint there is much to be gained by a better appreciation of operative limitations. A plea was entered for more careful diagnoses with an especial view to the detection of attending visceral disease; in short, to try and become more expert prognosticians. There are two phases of surgical practice alone, the careful observance of which would reduce the mortality of surgical operations so low as to cause us to believe that exactness had been reached. He referred to greater care in the detection of kidney lesions, and instituting measures to correct this frequent cause of unfortunate operative terminations, and the still prevalent practice of operating upon hopeless cases of cancer. It would seem that surgical limitation is most often exceeded and mortality unnecessarily increased in operations for the following diseases: General septic peri-

tonitis, extensive carcinoma of the ovaries, uterus and intestine, and operations upon the gall-passages in long-continued and profound cholemic patients without adequate preparation. He protested against the too frequent practice of operating in these affections. As to laparotomy in cases of general diffuse septic peritonitis, with irrigation and drainage, reports of such cases have appeared in literature from time to time, but the mortality up to the present time of such operations in exaggerated types of the disease is so great, in his opinion, as to make it an unwarranted procedure. He is strongly impressed with the belief that the successful cases reported have been cases of beginning general peritonitis, or of wide-extending, yet circumscribed peritonitis.

Excision of the External Carotid Artery in Cases of Inoperable Malignant Diseases of the Face.—DR. WILLIAM P. NICOLSON, of Atlanta, Georgia, reported 2 cases upon which this operation had been recently done. The first case was a sarcoma of the nose which began apparently as a polypus about 8 months before. The second case was one of inoperable sarcoma of the upper jaw of 3 months' duration, and of very rapid growth. It was claimed that in these cases the patient was simply doomed if nothing could be done, and this appeared to be the only recourse that offered any hope of benefit. He had performed various operations upon the external carotid artery in cases of malignant diseases, having tied the vessel 26 times, 4 of these being cases of double ligation. The operation has not been accompanied by any mortality. Little could be accomplished by simply ligating even both carotids, because the circulation was reestablished so rapidly that the nutrition could not be cut off with any degree of permanence. The operation of excision, as recommended by Dawbarn, seemed to be the only procedure that offered any hope; and while this would not perhaps produce much permanent effect, yet it seemed undoubtedly true that the lives of patients could be much prolonged, and their sufferings greatly lessened. The operation was one of considerable magnitude, and dealt with structures of great importance anatomically, yet the results demonstrated that there was comparatively little danger in the performance of it.

Autointoxication from Renal Insufficiency With or Without Disease of the Kidneys.—DR. JAMES T. JELKS, of Hot Springs, Arkansas, for years has made it a point to examine the urinary output for 24 hours of every patient who consults him. This has been a revelation to him, and therapeutics based thereon has enabled him to accomplish what he described as marvelous results. Abundant evidence was adduced to show that as the result of faulty elimination by the kidneys, without the presence of disease in these organs, patients may have vertigo, contracted capillaries, cold skin, especially of the extremities, so-called sick-headache, which is now recognized as uric-acid headache, melancholia, palpitation of the heart, interrupted heart-beat, various forms of skin diseases, rheumatism, gout, hysteria, epilepsy, and even genuine insanity. Among the remedies used to correct this faulty elimination are squills, milk, rectal or hypodermic injections of normal saline solution, digitalis or its derivatives, sodium phosphates, sodium salicylate, Vichy water, etc. All of these were used in connection with baths, where it was possible to give them, and the patients were ordered to drink from one-half to one gallon of hot water daily.

DR. GEORGE S. BROWN, of Birmingham, made (a) a supplementary report regarding a case of litholapaxy previously presented to the Association, and (b) a supplementary report with reference to a case of vesicorectal fistula.

DR. JAMES A. GOGGANS, of Alexander City, Alabama, reported one case of strangulated femoral hernia in a woman, 40 years of age; three cases of extrauterine pregnancy; one case of thoracotomy for empyema, and one case of ovarian cyst.

Some Life-Saving Measures in Obstetric Work.—By R. R. KIME, of Atlanta. The author considered as the most important life-saving measures saline infusions, medicinal remedies, serumtherapy, hydrotherapy, and drainage. In cases of placenta prævia and postpartum hemorrhage saline infusions or intravenous injections are of prime importance, not only to save life, but to lessen susceptibility of infection and hasten recovery.

Pseudomembranous Enteritis and Its Relation

to Abdominal Surgery.—DR. FRANK A. GLASGOW, of St. Louis, Missouri, called attention to this very common disease, and urged physicians to study the relations of it to appendicitis.

Solid Ovarian Tumor.—DR. JOHN G. EARNEST, of Atlanta, Georgia, reported a case of solid tumor of the ovary. The tumor showed the pearly luster of an ovarian tumor. It had so grown that it seemed to be caught under the promontory of the sacrum, and was adherent to the pelvic wall. It was enucleated with some difficulty. The pedicle was from the right side and comparatively small. The tumor, when removed, was found to be ovoid in its general outline, with an indenture corresponding to the promontory of the sacrum. It measured 20 cm. in length, and about 14 in breadth at the widest point. When cut open, its appearance was very much that of an ordinary uterine fibroid, and the tissue was quite dense. The cortex was united to the tumor by a thin layer of cellular tissue, infiltrated with serum. No microscopic examination was made. At first it was supposed to be a sarcoma, but careful examination showed the fibers to be distinct and arranged in irregular whorls, as in uterine fibroids, and the tissues quite as hard as any fibroid, and absolutely solid, without a break.

Histogenesis of Ovarian Dermoids.—DR. W. D. HAGGARD, JR., of Nashville, Tenn., stated that dermoid cystomas of the ovary differ essentially from dermoids in the orbit, pharynx, mediastinum, scrotum, coccyx, and elsewhere. The latter are unquestionably from inclusions or nipping off of the ectoderm in the development of the embryo, which is similar to the "healing in" of skin in wounds and the subsequent development of a dermoid growth. These structures all contain sebaceous material, hair, plates of bone, teeth, etc., and purely dermal derivatives. Ovarian dermoids contain derivatives of all the mesoderm and enteroderm as well, and hence some adequate explanation other than the inclusion of the skin-forming layer must be forthcoming. All sorts of curious theories have been successively advanced. The virginal pregnancy idea was succeeded by one which ascribed the origin of these growths to prolonged ungratified sexual desire on the part of the woman. A man who jested at his wife during travail was afflicted with a pregnancy (dermoid) of the thigh. In evidence an attempt at formation of nearly all the organs of the body has been found in the lawless development of these benign growths. Retinal pigment, more or less complete, optical vesicles, a rudimentary pharynx, with an attempt at the formation of an esophageal tube; the sympathetic nerves in the alimentary canal, and curiously enough a rudimentary uterus, with branching cells of the cervix and the glands of the fundus; mammae (one case of which underwent carcinomatous development). An easily recognized heart provided with valves was found by Johnston; and many other more or less perfectly formed organs and tissues other than dermal have been reported by investigators too numerous to individualize. These data have, as remarked by Clark, dealt a telling, if not fatal, blow to the inclusion theory of ovarian dermoid evolution. The researches of Kraemer and others seem to establish convincingly the ovulogenous theory of their development.

The following papers were likewise read and discussed: "Removal of Cystic Gallstone," by DR. HOWARD A. KELLY, of Baltimore; "Osteoarthritis of the Spine," by DR. MICHAEL HOKE, of Atlanta; "Epi- and Hypospadias, with Special Reference to the Operative Treatment," by DR. W. F. PARHAM, of New Orleans.

Much to the regret of the members, DR. W. E. B. DAVIS resigned the secretaryship, owing to the pressure of other duties, after having served the Association ably and efficiently from its organization to the present time. A resolution was offered and unanimously adopted, thanking Dr. Davis for his efficient services, tireless efforts, and faithful devotion to the interests of the Association during a period of 13 consecutive years.

Officers Elected for 1901: President, Dr. Manning Simons, of Charleston, S. C.; vice-presidents, Dr. George H. Noble, of Atlanta, Georgia, and L. C. Boshier, of Richmond, Virginia; Secretary, Dr. W. D. Haggard, Jr., of Nashville, Tennessee; Treasurer, Dr. F. W. McRae, of Atlanta, Georgia. Richmond, Virginia, was selected as the place for holding the next annual meeting; time, third Tuesday in November, 1901. At this meeting 29 new members were elected.

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended December 1, 1900:

Monday, November 26—Neurological Society.

Wednesday, November 28—County Medical Society.

Thursday, November 29—Pathological Society.

The Faculty Club of the University of Pennsylvania gave a dinner in honor of Dr. William Osler, November 15. The dinner was followed by a reception at the club house.

Dairy Inspection.—Drs. Abbott and Stewart, bacteriologists, and Col. J. Lewis Good, Chief of the Bureau of Health, are engaged in inspecting the various dairies which furnish milk to Philadelphia.

For Purer Water.—A filtered water reservoir and 5 filter beds will be located at Roxborough, Pa. Each bed will have a capacity of 15,000,000 gallons every 24 hours. The cost of this operation will be nearly \$250,000.

Diphtheria still prevails in the Thirty-fourth Ward of Philadelphia. The filthy condition of the streets is blamed for the trouble. The Bureau of Health has been notified of the condition, but has failed to remedy matters.

Hypnotism.—The people of Chestnut Hill, Pa., are highly indignant over an effort made by a newspaper reporter to obtain by hypnotic means, from a 12-year-old boy, a confession relative to the fire that has lately damaged that suburb.

Bogus Butter Indictments.—True bills were returned by the Philadelphia county grand jury recently against 16 offenders charged with selling oleomargarine. Many of the defendants are those rounded up by Dairy and Food Commissioner Cope in his raid about 2 months ago.

Diphtheria.—Because of the prevalence of diphtheria at Woodbury, N. J., the public schools have been closed until a thorough disinfection shall have been completed. For the month ended November 15, 133 cases of contagious diseases have been reported in Camden, of which 116 were diphtheria.

Michael Kepler, of Renovo, Pa., has been taken to the Kane Summit Hospital to undergo his fourteenth surgical operation within 3 years. Kepler fell and fractured several of his vertebrae 5 years ago. Since then he has been operated on at the Blossburg, University of Pennsylvania, Williamsport, and Kane Summit Hospitals.

Repeated Dislocations.—A young man applied to one of the Philadelphia hospitals for treatment for luxation of the shoulder-joint. He volunteered the information that this was the thirty-eighth time this shoulder had been dislocated. Luxation was easy, but the reduction was so difficult that an anesthetic had been given 28 times. The patient refused surgical correction.

Summer Cars in Trenton.—The Health Inspector of Trenton recently requested the local trolley company to discontinue the use of its summer cars. The city has no legal right to stop the use of these cars, but the Board of Health is of the opinion that open cars at this season of the year are a menace to the health of the community. The company promised to comply with the request.

University of Pennsylvania Medical Society.—At a meeting held November 16, Dr. DAVID L. EDSALL presented a patient with pulmonary tuberculosis, dextrocardia, and carcinoma of the stomach. He had been operated upon for the carcinoma, a gastroenterostomy being performed by Dr. Charles H. Frazier, with marked relief of his symptoms and a subsequent gain of 25 pounds in weight. DR. CHARLES H. FRAZIER presented a patient with cirrhosis of the liver who had been operated upon with complete relief of his ascites and other symptoms. Dr. A. O. J. KELLY presented 3 patients with aortic valve disease.

and spoke of the diagnosis of the condition. DR. JOSEPH SAILER exhibited **Bowles' 6 barrel stethoscope** and spoke of its advantages in ward class work. Dr. Sailer also demonstrated a method of **recording footprints**. The following officers were elected for the ensuing year: President, Dr. John H. Musser; vice-presidents, Dr. William G. Spiller and Dr. Alfred Stengel; secretary, Dr. A. O. J. Kelly.

Typhoid fever has become epidemic in Cementon, Pa. Out of 200 families composing the population, typhoid exists in 118, and in 22 families every member is prostrated by the disease. Lack of medical attendance is reported, the 2 physicians of the town being unable to attend all. The water-supply taken from the Lehigh river is thought to be the cause. If this is true many towns below Cementon may suffer from the disease.

Episcopal Hospital.—An appeal has been made for funds to pay the current expenses of this hospital, which were last year \$30,000 more than its receipts. Although it has received many gifts and legacies in trust, only the income can be used. The increase in practice and the extension of its area have added largely to the cost of maintenance. No patients have ever been excluded for want of funds during the 43 years of its existence.

Water Company in Court.—The New Chester Water Company is defendant in a suit in equity, the object of which is to compel the company to supply the city with water of a better quality than that which residents are compelled to use. The water is taken from the Delaware river, and the allegation is made by the complainants that it is unwholesome. The impurities are alleged to be partly responsible for the increase of typhoid fever during the year. The company contends that at the present rate of water rents it cannot afford a new filtering plant.

Vital statistics of Philadelphia for the week ended November 17, 1900:

Total mortality	CASES.	DEATHS.
Inflammation of appendix 1, bladder 1, brain 10, bronchi 6, kidneys 14, heart 1, liver 2, lungs 45, pericardium 1, peritoneum 6, pleura 1, stomach and bowels 13		439
Lungs—tuberculosis of 51, edema of 1		101
Marasmus 20, inanition 18, anemia 1, debility 7		52
Heart—diseases of 33, fatty degeneration of 3, neuralgia of 1		46

School Physicians Resolve to Organize.—Partial reports of the work of the school visiting physicians of Philadelphia, presented at their recent meeting, were said to show that the voluntary service has been so efficient that it furnishes the best of arguments in favor of a paid service, as in other cities. Complete returns, beginning with the establishment of the service in January last, are being prepared, which will still further demonstrate the preventive measures taken in scores of cases by which the community has been benefited. It was determined to form a permanent organization,

and a resolution was adopted requesting the Board of Education to grant the association the privilege of holding its meetings in a centrally located school building. Meanwhile a constitution is being framed by a committee. Communications were read from school medical inspectors in other cities relative to the work in such cities. In Chicago, it was stated, there are 50 inspectors, who are paid \$50 a month, and who daily visit the schools assigned them. It was claimed that fully 60% of the decrease of contagious diseases among school children since the establishment of the system in that city is due to the work of the medical inspectors. In New York, it was stated, there are 207 medical inspectors, who are each paid \$30 a month. Each inspector has 2 schools, and the work has been found of the greatest benefit to the community. The system of medical inspection of school children in Boston was said to have been begun in 1894. The city is divided into 50 districts, and one physician to each is appointed by the Board of Health. The visiting physicians are not permitted to prescribe, excepting for poor families unable to pay for medical service. In the cases of contagious diseases the inspectors are required to visit the residence of patients, see if they are properly isolated, and report thereon to the Board of Health. In no case, however, must there be any interference with the attending family physician. The physicians are each paid \$200 a year for their services. Like systems are about to be established in Washington and St. Louis. Philadelphia, it is said, is the only city having a voluntary corps of medical inspectors.

Philadelphia Pediatric Society.—November 13, 1900. DR. DAVID KIESMAN presented a case of **complete motor aphasia** in a child of 11 years, the result of infantile cerebral palsy; the child had had grip and pertussis in the first year of life, followed by convulsions in the second; she did not walk until 5 years old, and began to feed herself first at 7; at 9 years, epileptiform attacks began and have continued ever since, some being grand and some petit mal; there are traces remaining of a left-sided hemiplegia; the child has an intelligent face and understands everything that is said to her, but she has never spoken. Some authors object to "aphasia" being used to describe such cases in which speech has never existed, preferring the term "mutism"; the lesion affecting speech in children may be either right or left-sided; in this case the lesion is not clear, but was probably a bilateral meningeal hemorrhage. DR. ALFRED STENGEL exhibited: 1. A girl of 6 years, convalescent from **meningitis**; the attack came on suddenly with vomiting, headache, stupor, convulsions, mainly right-sided, and fever; on the fourth day the stupor and convulsions having continued, lumbar puncture, which withdrew 1 ounce of perfectly clear fluid, which was followed immediately by improvement, which has progressed; sight is still defective as the child runs into objects. 2. A girl of 12 years old with **osteoarthritis** affecting the small joints of the hand and feet; the hands are in the typical position of rheumatoid arthritis described by Charcot; the skiagraphs exhibited do not show marked changes in the joints; the previous history cannot be obtained satisfactorily. 3. A colored boy, 7 years old, with an **esophageal stricture** following the drinking of lye; a skiagraph, taken after the boy had been given several ounces of sirupy liquid in which half an ounce of bismuth was suspended, showed the diverticulum very well, the stricture being located 9 inches from the teeth. DR. J. P. CROZER GRIFFITH exhibited a girl 6 years old with symptoms pointing to cerebellar tumor; for 11 months there have been frequent headaches, spells of vomiting, staggering gait and some loss of weight, but the eyegrounds show no changes, nystagmus is absent and sensation and reflexes unimpaired. DR. S. M. HAMIL exhibited a **cretin** 6 months old, an Italian infant, under treatment for 1 month, with $\frac{1}{2}$ grain of thyroid extract 3 times daily; improvement has been marked, the tongue having receded and the collar of fat having nearly disappeared. DR. A. VAN HARLINGEN reported a case of **pemphigus** in a boy, the treatment, in addition to strychnin and whisky internally, consisted in opening the blebs and applying to them a lotion of mercuric chlorid 1:2000, one portion of the body at a time being so treated, the rest of the body being covered with an ointment of ichthyol or zinc; recovery ensued, and a subsequent relapse in which the above treatment was instituted at the start was mild.

Pittsburg Academy of Medicine.—At a regular meeting, held November 5, DR. P. J. EATON reported a case of *melenia* fatal 2 days after birth. DR. E. H. SMALL referred to a similar case reported by him to the American Medical Association 1 year ago which recovered. Consensus of opinion is that it is due to infection as evidenced by statistics from large maternities. The mortality is about 80%. DR. SMALL then read a communication from DR. ROSENBERRY, of Arbor Vitae, Wis., who stated that he had 4 fatal cases of *melenia* in 3½ years. DR. I. J. ELTERICH spoke of Winckle's and Buhl's diseases as closely related to *melenia*, but there is no jaundice in the latter. DR. J. C. THOMPSON related a case in which the urine was tinged with blood and meconium was mixed with blood-clots.

A symposium on **normal labor** was opened by DR. P. J. EATON, who spoke of the preparation of the patient and the management of normal labor. In R O. P. positions with extended head it is sometimes possible to get flexion by using knee-chest position. The tendency is to make more vaginal examinations than necessary, but in a certain class of cases internal manipulations are of value. Forceps in posterior positions usually slip; may be put on reversed. The most important point in connection with forceps is that the pressure and traction be intermittent. DR. I. J. ELTERICH spoke on the care of the newly-born infant, and emphasized the importance of prophylaxis and the gain to the child if the cord is not tied before pulsation in it ceases. DR. E. B. HECKEL spoke on ophthalmia neonatorum. Statistics are unreliable both as to its frequency and as a cause of blindness. Actual infection of the eyes takes place after the passage of the head. Every case is not due to gonococcus alone. Credé method (10 grains to 1 ounce) is efficient in the way of prophylaxis. As to treatment, flush out every 30 minutes with normal salt-solution or potassium permanganate, 1 to 1000, and use ice-compresses. Apply silver nitrate, 10 grains to 1 ounce, once daily, and later decrease to 5 grains to 1 ounce.

In discussion DR. T. G. SIMONTON referred to medullary anesthesia in labor. DR. J. I. JOHNSTON said he was in the habit of having the prospective mother practise micturition before labor while lying on her back with a view of dispensing with the use of the catheter after labor. DR. J. D. SINGLEY said that the vigorous use of antiseptic solutions as HgCl₂, 1:5000 in gonorrheal conjunctivitis was certainly injurious. Mechanical cleaning with normal salt-solution is preferable. It will wash out gonococci and it will not set up a chemical conjunctivitis upon which the bacteria may thrive. DR. WILLETTTS said the indiscriminate use of Credé's method had probably done much harm. Gonococci can be washed out with sterile water as demonstrated by Knapp of New York. He relies on protargol 10 grains to 1 ounce and cold compresses. DR. J. C. DUNN said that many women practise massage of the abdomen with some emollient, claiming it makes them more comfortable. A proper amount of exercise is essential to a pregnant woman. DR. BURLEIGH related a fatal case of hemorrhage from ligated cord. DR. HUGGINS referred to a case of ophthalmia neonatorum in which solution of silver nitrate from 10 to 40 grains to the ounce had been used with recovery. DR. J. J. SIMPSON spoke of the case of a woman curetted for supposed malignant disease of the uterus, by her physician. Later the condition was found to be due to pregnancy and she was delivered of a child at term in spite of the previous cureting. DR. CAMERON said he did not consider it necessary to examine urine of pregnant women so frequently, provided nothing had been found at first examination, and patient had no symptoms of kidney involvement. His patients would not submit to a personal examination prior to labor. It is unwise to attempt to dilate cervix with fingers, membranes and head do it better. The fewer vaginal examinations made the better. A douche prior to labor, if conditions are normal, is harmful, and the same may be said of it after labor. DR. C. O. GOULDING stated that we are frequently in too much of a hurry to deliver the placenta. Wait until it is completely detached by the normal uterine contractions. Forceps are applied too often and too early. A case of mammary abscess was reported due to mother's habit of applying saliva to nipples. DR. I. J. MOYER inquired as to the various causes of ophthalmia neonatorum in addition to gonococci. DR. E. H. SMALL said he had seen it suggested that in case the mother has gonorrhea it is well to leave membranes intact. He uses a plain douche of hot water several days after labor.

Closing, DR. HECKEL said the condition of the conjunctiva is the index to the strength of the solution of silver nitrate, but he never uses one stronger than 22 grains to the ounce. It is never justifiable to use the solid stick. He did not believe in using any irritating solution to flush out an eye—use sterile water or warm salt-solution. DR. EATON insisted that the examination of the patient prior to labor is important. He could not see that a preparatory douche could do any harm. He also related the case of a patient curetted while pregnant by a prominent gynecologist and who was delivered at term.

NEW YORK.

"Through the First Antarctic Night" is the title of a volume recording the experiences of Dr. Frederick A. Cook, of Brooklyn, who accompanied the Belgian Antarctic Expedition in 1897 as surgeon.

A New Hospital.—The sisters of the Holy Family of Nazareth, of Chicago, will erect a hospital which will cost \$250,000. It will be equipped throughout according to modern ideas, and will occupy an entire block.

Dr. Emmet.—Dr. Thomas Addis Emmet is reported to have resigned from the staff of the Woman's Hospital of New York. Dr. J. D. Emmet, his son, is acting temporarily in his stead, though no successor has as yet been appointed.

A Post-office Physician.—Minneapolis enjoys the distinction of having a post-office physician. His duties consist in giving free medical aid to all civil service employes, inspecting the various branch offices as to their sanitary condition, etc. It is a civil service appointment.

Garbage Removal Contract.—During the absence of the Democratic Mayor of Utica, N. Y., the Republican council compelled the Board of Health to resign, and appointed a new one in its stead. The object was to secure the execution of a garbage removal contract before the present councilmen go out of office.

Buffalo Academy of Medicine.—The section of ophthalmology, otology and laryngology met November 19. The program was as follows: Exhibition of a Case of Total Removal of Thyroid Gland by Dr. Cott. Discussion: The Relation of Tuberculosis of the Larynx to Pulmonary Tuberculosis. The discussion was opened by Dr. De Lancey Rochester, followed by Dr. E. L. Shurley, of Detroit, Mich., and Dr. John H. Pryor.

The new State Asylum for Insane Criminals at Dannemora, N. Y., was opened November 15. Dr. R. B. Lamb, for 4 years assistant superintendent at Matteawan, has been appointed superintendent with Drs. M. L. Bird and A. T. Baker as assistants. A transfer of 58 convicts has been made from Matteawan and in the future all of the insane male convicts convicted of felony will be sent there from the State prisons, penitentiaries, and reformatories instead of to Matteawan.

Resident Physicians Wanted at Craig Colony.—Two recent graduates in medicine are wanted to serve six months or a year at the Craig Colony for Epileptics, at Sonyea, Livingston County, N. Y. The position affords a rare opportunity for studying epilepsy, as well as a good general experience in medicine and surgery. Board, washing, and lodging are furnished, but no pay. Address Dr. Wm. P. Spratling, Medical Superintendent, Sonyea, Livingston County, N. Y.

Dangers of Rabies.—It is reported that a commissioner on the Board of Health for Greater New York has given out the following: "The Department of Health desires to call the attention of physicians and others to the occurrence of the number of cases of rabies among dogs throughout the city, and would request that wherever persons are bitten by strange dogs or stray dogs they immediately consult a physician and have their wounds cauterized, and then if there is any question as to the existence of rabies in the animal communicate at once with the Department of Health."

The New York State Veterinary College on the Cornell campus was partially destroyed by fire, November 13. The entire loss will probably amount to \$50,000. The department of histology lost specimens and apparatus worth not less than \$10,000, while the loss of the department of bacteriology cannot be covered by \$15,000. The greatest loss sustained is that of the specimens of these 2 departments. The laboratory of Professor Gage, the head of the department of histology, contained all his specimens, the work of more than 20 years. A temporary roof has already been put on the building, the museum will be used as a laboratory and the work will proceed.

Dr. Lewis Albert Sayre.—The New York Pathological Society loses the last of the members who brought it into existence, by the death of Dr. Sayre. The first meeting of the society was held in his office June 14, 1844, Drs. George A. Peters and Middleton Goldsmith participating in the formation of the new society. Dr. Sayre kept his interest in the society alive, occasionally attending its meetings, until the end of his professional activity. It is with a special sense of loss that the society sees fade from its list of active members this illustrious name, enrolled at its first meeting when "the oldest pathological society in the world," as he was fond of saying, was created. The Society now records upon its minutes the death of DR. LEWIS ALBERT SAYRE, and adopts the following resolution:

Resolved, That the sympathy of the New York Pathological Society be extended to the family of Dr. Sayre in their bereavement, and that the above testimonial be published in the current medical periodicals.

Decennial Anniversary.—The Class of 1900, Physicians and Surgeons, Medical Department, Columbia University, celebrated its decennial anniversary by a dinner, at the New York Athletic Club, November 15. This is believed to be the first class celebration in the history of the Physicians and Surgeons. Dr. H. B. Brown, toastmaster, called upon Dr. James Pederson to respond to the Class; Dr. C. W. Townsend, the College; Dr. A. E. Gallant, a Retrospect and Historic Report of the Class; Dr. Wm. Gilfillan, the Decennial Dinner; Dr. A. W. Hollis, Clinical Medicine; Dr. P. R. Bolton, Modern Surgery; Dr. C. I. Proben, Medical Testimony; Dr. H. P. de Forest, Commercialism in Medicine; Dr. H. L. Palmer, What Measure of Success Should a Physician Achieve in Ten Years' Practice?; Dr. C. F. Chapman, the Physician in the Country; Dr. S. A. Twinch, Town vs. Country Practice; Dr. E. W. Peet, Philanthropic Work of the Physician; Dr. H. H. Forbes, Requirements Necessary for Success in Our Profession. Arrangements will be made for a reunion in 1905.

Physicians Discuss Milk.—In response to a call of a committee of the Medical Society of the County of New York, a meeting was held recently at the Academy of Medicine to discuss the best method of improving the milk-supply of New York. The meeting was attended by nearly all the prominent dairymen of the city. The plan outlined is to have a competent bacteriologist examine the milk-supply of any dealer who wishes such examination, and if it comes up to the standard set, to issue to such dealer a certificate which will recommend his milk to the public. Dr. Chapin read the set of rules proposed by the Medical Society for reforming the dairy farms. The rules not only provided for cleanliness in stabling and in storage, but insisted upon every cow being thoroughly cleansed each day, on the milker washing his hands and cleaning his nails before milking, and upon precautions being taken against subjecting the cow to any excitement. The society will endeavor to aid the Board of Health in having dealers in milk preservatives arraigned in court. The general sentiment of the dairymen present seemed to favor the plans of the physicians.

The New York State Tenement House Commission.—This commission was created by the Legislature for the purpose of investigating the tenement house problem, and has the power to summon before it witnesses who may be in a position to give information as to existing conditions and offering suggestions as to remedies. "The Relation of Tuberculosis to the Tenement House Problem" was discussed at a recent meeting in New York City, and physicians working among the poor in the tenement districts were heard.

Dr. John H. Pryor, of Buffalo, said that conditions in the tenements in Buffalo at present were much superior to the conditions in New York City, because in Buffalo there were some light and fresh air in the tenements, while in New York there was practically neither. He said the majority of the persons living in tenements had tuberculosis in some form and that there were probably 20,000 tuberculous individuals in New York City alone. He said that in every tenement there should be at least 600 cubic feet of air for each inmate, and that some tenements were so infected that they ought to be demolished. Dr. Herman M. Biggs said there were 9,000 deaths from tuberculosis in New York City annually. He said the causes of tuberculosis were the unsanitary conditions in the tenements, the overcrowding, the poverty of the inhabitants, and the infection of the houses themselves. He recommended a change in the construction of tenement houses. More fresh air and more light were required.

NEW ENGLAND.

The Boston Health Report for the week ending November 14 shows 145 cases of diphtheria, scarlatina 33, measles 18, and 19 of typhoid fever.

The Veterinary School and Hospital of Harvard University will be permanently closed June 1, 1901, in accordance with a vote of the corporation.

Free Vaccination.—The board of health has passed a vote for the free vaccination of public school children in Indian Orchard, Mass. This action was taken under a law passed in 1894 giving local boards of health authority to order free vaccination when they deemed it expedient.

Massachusetts Pure Food Law.—According to the annual food and drug inspection report of the Massachusetts Board of Health, the law of that State forbidding adulteration has brought about a marked improvement. This is especially true of butter, condensed milk, species of condiments, coffee, molasses, maple syrup, and maple sugar, honey, confectionery, and canned goods. The percentage of adulteration in these articles is much lower than a few years ago; but in wheat flour, spirits, wine, beer, and cider, drugs, jellies, and jams, a good deal of adulteration is found. Within the past few years, adulteration has found in jellies and jams a fruitful field of operation. The tendency to cheapen the product has led to the introduction of glucose instead of cane sugar, of cheaper instead of more expensive fruits, and of anilin dyes to imitate the color of genuine fruits.

CHICAGO AND WESTERN STATES.

The Cleveland College of Physicians and Surgeons has received a gift of \$10,000 from John D. Rockefeller, to be added to the building fund.

Smallpox on Alaska Steamer.—The steamship *Topka*, recently from Alaska, has been detained in quarantine at Port Townsend, Wash., because of smallpox on board.

Oshkosh Schools Closed.—The prevalence of diphtheria and typhoid fever in Oshkosh, Wisconsin, is so great that the authorities have determined to close the schools, both public and parochial.

The Oklahoma Medical Association held its annual session in Oklahoma City, November 15. About 100 leading physicians of the territory were present, and the meeting was the most successful one in the history of the association.

Fraudulent Medical Certificates.—The United States Court at Leavenworth has found guilty one Dr. H. Wilson, of Randolph, Kan., for advertising blank medical certificates for sale to any who would buy. The charge was for a fraudulent use of the mail.

Family Poisoned.—Either pickles or meat eaten by the family of Mr. Tilly, of Lake Bluff, Illinois, caused severe symptoms of poisoning. After the meal they became violently ill, the father and mother delirious. At present they are said to be out of danger.

Indianapolis City Hospital.—Dr. C. H. Poucher, who has been superintendent of this hospital for the past 3 years, has resigned on account of ill health. The vacancy has been filled by the appointment of Dr. M. J. Spencer, formerly superintendent of the City Dispensary.

The Medical Society of City Hospital Alumni, of St. Louis, Mo., met November 15. A paper was read by Dr. Ludwig Bremer, entitled "The Treatment of Chronic Nephritis," and one by Dr. Charles Orr, entitled "The Removal of Tonsils, with Special Reference to the Use of the Farlow Punch."

Christian Science Victim.—Mrs. A. D. McNeil, of Cheyenne, Wyoming, is reported another victim of christian science. She had been ill for some time, grew gradually worse, and died under the ministrations of a devotee of christian science who locked the door against the physician who had been in attendance.

St. Louis Academy of Medical and Surgical Science.—At a recent meeting the following officers were elected for 1901: President, Dr. Emory Lanphear; senior vice-president, Dr. Carl Pesold; junior vice-president, Dr. H. S. P. Lare; secretary, Dr. O. L. Suggett; treasurer, Dr. G. M. Phillips; orator, Dr. Wm. Porter; librarian, Dr. H. G. Nicka.

Quarantines Against the Chinese.—Chinese emigrants coming through California still have the bubonic plague quarantine act of Colorado enforced against them. Unless the emigrant has a certificate showing that he has not been exposed to plague during the 6 weeks immediately preceding, the railroad officials are not allowed to land him in Colorado.

Ambulance Corps Returns.—The members of the Chicago Irish Ambulance Corp. sent out to aid the Boers in South Africa arrived in New York, November 15, on the steamer *Trave* from Bremen. They arrived in South Africa about April 30 last, and left the Boer army in the vicinity of Lorenzo Marquez, from whence they sailed for Trieste and thence to Bremen.

The Southern Illinois Medical Association held its first session at Murphysboro, Ill., November 15, Dr. W. F. Grinstead in the chair. Prof. G. H. French, of the Southern Illinois Normal University, discussed "Epilepsy and Some Other Intestinal Parasites." A paper was read by Dr. J. S. Wiggins, of East St. Louis, entitled "Is the Diagnosis of Appendicitis Free from Error?"

Company Sued for Damages.—Edward J. Hempker, a moulder, sued the Dayton Malleable Iron Company for \$25,000 damages for the loss of both eyes. A peculiarity of the suit is that it is based on the employment of Hungarians by the company. Plaintiff alleges that the Huns did not understand the English language, and that they did not obey orders given them on that account.

Vaccination Contest in Duluth.—The District Court has granted a writ of mandamus requiring the superintendent of schools to show cause why children who have not been vaccinated should not be admitted to the public schools. At the instance of the local health commissioners the superintendent recently issued instructions that unvaccinated children should not be allowed to attend school.

New Use of Telephone.—Indianapolis telephone subscribers are said to have made arrangements with the central office to have their telephone bell act as an alarm clock, to enable them to catch early trains. Subscribers have left word to be called at one-hour or two-hour intervals during the night when they have to take medicine, and much inconvenience and worry has been saved thereby.

Diphtheria from Rabbits.—An epidemic of this disease prevails in Grafton, Ill. Churches, schools and courts have temporarily suspended action and a quarantine has been established. Over 100 cases and 20 deaths are reported. Many rabbits infest the surrounding country and they have been largely used as food by the people of the town. Recently hundreds of dead rabbits have been found in the country and a microscopic examination revealed the fact that they died from diphtheria. Physicians believe that these animals are the cause of the epidemic.

Poison in Foods.—Dr. E. E. Hunter, assistant physician and chemist to the Board of Health of St. Joseph, Mo., has by chemic examination found dangerous adulterants in certain foodstuffs sold by local grocers. He is now making strenuous efforts to secure the passage of an ordinance empowering him to inspect such foods and to prohibit their sale in the city. Jellies, fruit, jams, etc., were found to be colored by anilin. Evaporated fruit was found to contain zinc oxid in such quantities as to make it dangerous, and the French canned peas on the market are said to contain copper.

An Employment Bureau for the Blind, said to be the first of its kind, is to be established in Grand Rapids, Michigan, and to be maintained partly at State expense. It will be more than an employment bureau, in the ordinary meaning of that term, as its officers will visit the blind of the State outside of institutions, learn their conditions, what they can do, what ability they have for learning and their willingness to aid in supporting themselves. Miss Roberta Griffith, who will have charge of the work, is herself blind. It is also the idea of the promoters to place more children in the State School for the Blind.

Pure Water in Chicago.—This city rejoices in its added chances of longevity following the completion of the drainage canal. All the sewage of the city has not yet been diverted from the lake, out of which the supply of water for domestic purposes is taken, but already there is a very comforting diminution in the death-rate, particularly marked in the statistics as to typhoid fever. In 9 months after 2 of the main sewers were caused to empty into the river, instead of the lake, there was an improvement of 50% in the sanitary quality of the water as compared with the same period the year before. The improvement, as shown by chemical analyses, has extended to all the cribs. The number of deaths amounted to 44% in 1900 from 1899, and 51.4% in 1900 from 1898. The total number of deaths for last October was 1.802, which is a monthly death rate of 1.06%, the lowest October death-rate in 10 years.

Hospitals Seek Aid.—The secretary of the Hospital Saturday and Sunday Association recently reported that 12 hospitals had filed sworn statements of the charity work done by them for the year ended September 30. It is said the statements were filed with a view to participating in the distribution of the sums contributed December 1-2. The institutions are St. Luke's, Protestant, St. Mary's Infirmary, St. Louis Baptist, Mullanphy Hospital, Missouri Baptist Sanitarium, Evangelical Deaconess, Bethesda Incurable, St. Louis Children's, Martha Parsons, Good Samaritan, and St. John's Infirmary. Of these hospitals 8 have filed with the secretary resolutions adopted by their boards of management, agreeing to comply with the constitution and by-laws of the association. To the remaining 4 a notice has been sent instructing them to do likewise before December 1. Of the hospitals mentioned 10 participated in last year's distribution. The Hospital Association is strictly nonsectarian and almost every religious denomination is represented in its membership.

Emergency Rations Test.—Capt. Fred W. Foster and 25 troopers of the Eighth United States Cavalry have left Fort Reno, O. T., for a 10 days' march through the Caddo Indian country, to make a second test of the emergency rations. The test will be a novel one, as the 3 cakes of sweet chocolate, which constituted a part of the rations tested on the march to Fort Sill, will be omitted, and a preparation composed of condensed milk will be substituted. They will also make a more severe test of a meat compound, a food preparation prepared under the direction and supervision of the War Department. Capt. Foster is of the opinion that the condensed-milk food will prove to be a great success, and give better satisfaction than the chocolate, which was of little service during the test just completed. The milk food is made up in the form of wafers, and, when dissolved with water, forms a kind of soup. Soldiers who have tried the preparation say it is palatable and affords considerable nourishment. A detailed report of both tests will be sent to the War Department soon by Capt. Foster.

SOUTHERN STATES.

St. Mary's Seminary, at St. Mary's City, Md., has been quarantined because of scarlet fever.

The Washington Ophthalmological and Otolological Society held its thirty-fourth session at the office of its president, Dr. S. O. Richey, November 13. The meeting was one of two business meetings of the year.

The New Municipal Hospital.—About 31.7 acres of land opposite Petworth subdivision has been purchased by the Commissioners of the District of Columbia as a site for the new municipal hospital. The total cost is \$63,400. The Commissioners were allowed \$100,000 for this purpose by the current District Appropriation Act.

The Smoke Nuisance.—It is reported that the District Commissioners of Washington City will take legal steps to enforce the smoke law passed by Congress, which prohibits the emission from the chimney or smokestack of any stationary engine, steam boiler or furnace, of dense black or gray smoke or cinders. A reasonable time was given the proprietors to properly equip the plants, but they have failed to do so.

Removal of Dead Animals.—An ordinance has been introduced in New Orleans making it the duty of the owner of any bovine or equine animal, within 3 hours after the death of such animal, to cause the body to be removed to some licensed place of rendering. The body must be conveyed in a vehicle suitable for the purpose and so constructed as to hide the body from public view. The vehicle and body must be deodorized before removal, and the body must not be carried along Canal street. The usual penalties are attached to the ordinance.

Experiments with Bacillus Typhosus.—Professor William Royal Stokes, city bacteriologist and professor of pathology of the University of Maryland, has just completed a long series of experiments with typhoid bacillus, which were led by him in large quantities and continuously to dogs, cats, pigs, calves, white rats, guineapigs and rabbits. They remained perfectly healthy. Cultures were also taken from the animals every day, but no colonies of typhoid bacilli were ever obtained from them. The conclusion reached by Dr. Stokes is that the typhoid bacillus cannot maintain its struggle for existence in the intestines of any of the animals experimented upon.

Yellow Fever Serum.—Dr. Angel Bellinzaghi, the young Italian specialist who has had such remarkable success with his yellow-fever serum, has been in San Antonio, Tex., recently, arranging for a stock farm for the production of the serum. Dr. Bellinzaghi said: "I would establish here a vaccine and serum farm because of the climate, which should be well adapted to the production of the serum I want, and because of its nearness to Mexico, my field of work next year. My idea is to operate the farm upon a scientific basis from a medical standpoint and by a company capitalized with a half million dollars, which I am confident can be done. When I have looked over the ground more carefully I can unfold my plan in greater detail."

CANADA.

The Fox Bay settlers who removed to Garland, Manitoba, after their eviction by M. Menier, are reported to be in a deplorable condition. Moving as they did in the hottest month of the year the change of climate affected them severely, and an epidemic of typhoid swept away 8 of their number. They arrived too late to do any farming, and have practically no provisions for the winter nor proper houses in which to live.

MISCELLANY.

Smallpox Aboard Steamer.—The Royal Mail steamer *Don*, from Southampton, October 31, arrived at Kingston, Jamaica, November 16, and was placed in quarantine because of smallpox on board.

Medical Department of the Army.—Majors Valery Harvard, William C. Gorgas, and J. R. Kean, surgeons, have been detailed to represent the medical department of the army at the Pan-American Medical Congress to meet in Havana, Cuba, December 26-29, 1900.

Insane Soldiers From the Philippines.—The Government Asylum at Washington, D. C., recently received 13 insane soldiers from the Presidio Hospital at San Francisco, Cal., where they have been detained since their arrival from the Philippines.

X-Ray Not Evidence.—It has been decided that hereafter the x-ray will not be sanctioned by the American Medical Association as a part of expert evidence, and whether or not a limb has been properly set will be determined by the ability of the patient to use the member.

Membership in the International Sociological Institute of Paris.—Dr. Edward A. Ross, chief of the Department of Economics and Sociology at Leland Stanford University, has been elected an associate member of the International Sociological Institute of Paris. Dr. Ross is now one of 6 such members in the United States.

Captain Meyers.—A report has been received by Admiral Van Reypen, surgeon-general of the navy, concerning the wounding of Capt. Meyers, the ranking marine officer at Pekin. The wound proves to have been made by a Chinese spear and is one of few wounds from such a weapon that American surgeons have been called upon to treat. Capt. Meyers is recovering.

Quarantining at Havana.—The Havana papers are now generally commenting upon the action of the Government in the matter of quarantining immigrants and a movement is on foot among the Spaniards to form an association to work in conjunction with the Government in encouraging immigration from Spain and the Canaries, and to provide for immigrants on their arrival.

The new Minister from Argentina to the United States. Dr. Eduardo Wildo, held the post of President of the Argentine National Department of Hygiene. He planned most of the medical colleges and hospitals throughout Argentina and has won distinction as a medical writer. His first diplomatic work was the negotiation of the Sanitary Convention between Argentina and Uruguay in 1872.

Obituary.—LLOYD DORSEY, of Washington, D. C., November 13, aged 74.—GEORGE K. CROSTHWAITE, of Hamilton, Ont., November 15.—CHRISTOPHER T. AHLSTROM, of New York, November 14.—SALOME MERRETT, of Somerville, Mass., November 7, aged 57.—NATHANIEL P. RICE, of New York, November 10, aged 72.—THOMAS A. QUAYLE, of New Orleans, November 16, aged 31.—HORACE TRACY HANKS, of New York, November 18, aged 64.

Disease Among Alaskan Indians.—The United States Commissioner at Nome, Alaska, says that unless the Government extends aid to the Alaskan Indians this winter the death-rate must be exceedingly large. He says hundreds of natives in the Yukon Valley are dying of tuberculosis. During the summer the Indians were unable to dry fish, which is their chief and almost only staple. The matter will soon be brought before the Department of the Interior.

"Christian Science" Defined.—There were some compensations for the huge advertisement which the Episcopal church congress in Providence this week gave to "christian science" by devoting an evening to a discussion of its pretensions and claims. One of them was the neat definition of eddyism by a speaker named Rogers. "It is something," said he, "of which the part that is true is not new, and the part that is new is not true."—[*Springfield Republican*.]

Disinfection of Lepers' Mail.—Dr. Carmichael, of the Marine-Hospital Service at Honolulu, has instituted the following plan for disinfecting the mails from the leper settlement at Molokai. All mail from this settlement will be disinfected with sulfur dioxide at the settlement, and then transferred directly to the steamship and received aboard in clean and disinfected sacks furnished by the post-office authorities. These sacks will be disinfected with formaldehyde at Honolulu before the mail has been removed. All letters are perforated or the corners clipped at the settlement before disinfection. No case of leprosy, the surgeon reports, has yet been discovered among the post-office employees, although non-disinfected mail from the leper settlement has been handled by them for many years.

Women Dipsomaniacs.—The Supreme Court has heard a test case concerning the commitment of women dipsomaniacs to insane hospitals, a complaint having been entered that such commitments under the present statute are not in accordance with the Constitution of the United States. The council for the complainant maintained that while men have a hearing before commitment, that privilege is not extended to women. After hearing expert witnesses the Court committed the complainant on an allegation that she was an habitual drunkard.

Pure Food Legislation.—At a meeting of the National Grange, Patrons of Husbandry, at Washington, D. C., November 16, George L. Flanders, Assistant Commissioner of Agriculture of New York State, endorsed the Grout Oleomargarine Bill now pending before Congress, and advocated proposed legislation protecting State trade-marks for cheese, and legislation to prevent frauds in the manufacture and sale of all dairy products. Aaron Jones, of Indiana, pointed out what the organization was doing to promote various legislative matters. About 60 agricultural chemists attended the meeting as a body. Mr. Wiley, of the Agricultural Department, complimented the Grange on its influence in the interest of pure food legislation, and detailed the Department's work in meat investigations for the protection of the American market, and our commercial reputation abroad.

Smallpox.—About 30 cases of this disease have been reported at Washburn, Wisconsin, and 5 cases are at present in the pest house. One whole family living near Washburn are down with the disease. The house is well quarantined. One case is reported at La Crosse. The pest house there had not been used for so many years that it took some time to prepare it for the patient. No new cases are reported from Prince George's County, Md., and the present victims to the disease are doing well. Dr. L. A. Griffiths says that every case of smallpox that has been in the county for the past 5 years, including the first case of the present outbreak, has been traced to the District of Columbia. The disease is reported to prevail in a mild form in Sprague, Washington. Several families are quarantined. From Thornton, Washington, 12 cases are reported. The authorities have employed trained nurses to take charge of the patients.

Government Hospital for the Insane.—In the report of the Board of Visitors, recently submitted to the Secretary of the Interior, attention is called to the overcrowded condition of this institution at Washington, D. C. At the latest session of Congress authority was given for the extension of the hospital for the accommodation of 1,000 additional patients, and plans for the new building are already under way. The report states that the building will at present accommodate conveniently about 1,600 patients, with the necessary employees. The number on June 30 of this year was 2,076. The inconvenience and actual menace to safety resulting from this condition, declare the Visitors, can scarcely be realized by those who have not felt the responsibility for these helpless patients. In some of the wards for males, which are intended for 18 patients each, 44 patients are now confined. In other wards for males, from 16 to 18 beds are made on the floor each night along the corridors. In the wards for the most disturbed class of female lunatics, with a normal capacity of 36 each, there are now 48 to 60 patients. During the year covered by the report many improvements were made at the institution, but much yet remains to be done. A new laundry has been installed, and a complete sewer system from all parts of the institution to the river has been built. One of the great needs of the hospital is better protection from fire; for this an appropriation of \$37,000 has been made by Congress. The Visitors object to the site chosen for the new buildings and recommend that the ground known as Wilson Park be chosen.

Suicide and Homicide in the Army.—The tabulations of the cases of suicide and homicide which occurred in the army during the years 1898 and 1899 are compared in the annual report of Surgeon General Sternberg with the cases which occurred during the 10 years, 1888-97. Contrary to the general anticipation, it is found that there were among the troops during the past 2 years relatively fewer homicides than during the years of the previous decade, and that the

mean annual ratio of suicides per thousand men was about $2\frac{1}{2}$ times greater during the decade of peaceful garrison life than during the recent period of active military service. The following figures show the rates for these years:

Year.	Mean Strength.	SUICIDES		HOMICIDES.	
		Number.	Ratio per Thousand.	Number.	Ratio per Thousand.
1888	26,789	8	.30	5	.19
1889	27,206	21	.77	5	.18
1890	26,684	16	.60	7	.26
1891	26,460	22	.83	8	.30
1892	26,861	22	.82	5	.19
1893	27,659	22	.80	5	.18
1894	27,674	18	.65	10	.36
1895	27,326	19	.70	1	.04
1896	27,183	12	.44	4	.15
1897	27,374	10	.37	5	.18
Mean of Decade .	27,116	17.0	.63	5.5	.20
1898	147,795	38	.26	19	.13
1899	105,546	30	.28	23	.22

Health-Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General, U. S. Marine-Hospital Service, for the week ended November 17, 1900.

Yellow Fever.—Dr. John Guitéras, professor in the Medical University of Havana, holds an appointment under Gov. Gen. Wood as yellow fever expert for Havana. In a recent interview he said: "There is no more yellow fever in Havana this year than in former years. More has been heard of it in the States on account of the number of Americans who are in Havana. There were 24,000 Spanish emigrants landed in Havana last winter, and it has been among them that the fever has spread this summer. This winter, 300 have arrived from Spain, but we have not allowed them to enter Havana, having erected barracks just outside of the city where they are kept until they are sent to the interior of the Island. I believe that yellow fever will be stamped out in Havana in the course of the next 2 or 3 years. There is no reason why it should exist now, if proper precautions are exercised. There was no yellow fever in Matanzas or Santiago this summer, and only a mild form in Havana. Every house in Havana will be fumigated this winter, and if the dormant germs can be exterminated there will be little or no fever in Havana next summer."

Changes in the Medical Corps of the U. S. Army, for the week ended November 17, 1900:

HATCH, H. W., acting assistant surgeon, will report at Fort St. Michael for duty as post surgeon.

CUSHMAN, GABRIEL, hospital steward, will be sent from Camp Skagway to Port Valdez, Alaska, to relieve Hospital Steward Clinton F. Henderson.

HENDERSON, CLINTON F., hospital steward, upon relief at Port Valdez, Alaska, will report for duty at Camp Skagway.

THOMPSON, Major HENRY D., surgeon, is granted leave of absence until November 25.

HESS, First Lieutenant LOUIS T., is granted leave of absence until November 30.

LEWIS, JOHN C., acting assistant surgeon, will proceed to his home, Georgetown, Ky., from where he will report to the Surgeon-General of the Army for annulment of contract, on account of physical disability.

WHITE, JONAS S., acting assistant surgeon, will proceed to his home, Manheim, Pa., from where he will report by letter to the Surgeon-General of the Army for annulment of contract, or orders.

DEMEX, C. F., acting assistant surgeon, is granted leave of absence until November 30.

LYSTER, First Lieutenant T. C., assistant surgeon, is granted leave of absence for 1 month, with permission to go beyond the limits of the division of Cuba.

BENTLEY, CARLE E., acting assistant surgeon, in addition to his duties at Fort Logan H. Roots, will perform the duties of examiner of recruits at Little Rock, Ark.

STARK, Captain ALEXANDER N., assistant surgeon, is granted extension of leave, to include October 29.

MEARNS, Captain EDGAR A., is granted 6 months leave of absence, on surgeon's certificate.

RICHARDS, First Lieutenant WM. E., assistant surgeon, leave of absence, granted August 31, is changed to leave for 3 months on account of sickness.

GOMEZ, VINCENT, acting assistant surgeon, is relieved from duty in the division of Cuba, and will proceed to Santiago, Cuba, and report by letter to the chief surgeon, division of Cuba, for annulment of contract.

COOKE, ROBERT P., acting assistant surgeon, is relieved from duty in the division of Cuba, and will proceed to Boyce, Va., and report by letter to the Surgeon-General of the Army, for annulment of contract.

COONEY, DANIEL C., acting assistant surgeon, is relieved from duty in the division of Cuba, and will proceed to Washington, D. C., and report to the Surgeon-General of the Army for annulment of contract.

GOULDING, TIMOTHY F., acting assistant surgeon, is relieved from duty in the division of Cuba, and will proceed to Washington, D. C., and report to the Surgeon-General of the Army for instructions.

HAYARD, Major VALERY, surgeon, is detailed to represent the medical department of the Army at the Pan-American Medical Congress to meet in the city of Havana, Cuba, December 26-29, 1900.

GORGAS, Major WM. C., surgeon, is detailed to represent the Medical department of the Army at the Pan-American Medical Congress, to meet in the city of Havana, Cuba, December 26-29, 1900.

KEAN, Major JEFFERSON R., surgeon, is detailed to represent the Medical department of the Army at the Pan-American Medical Congress, to meet in the city of Havana, Cuba, December 26-29, 1900.

CARR, Major LAWRENCE C., surgeon, orders of November 2 are so amended as to direct him, upon his relief from duty in the division of Cuba, to proceed via Havana, Cuba, to Washington, D. C., and report to the Surgeon-General of the Army for instructions.

ECHAVEARRIA, Major RAFAEL, surgeon, is honorably discharged from the service, to take effect November 30, his services being no longer required.

FOGO, JOHN S., acting assistant surgeon, will proceed from Biddeford, Me., to Fort McHenry for temporary duty.

VAN HOFF, Major JOHN R., surgeon, having arrived at San Francisco, will proceed to Chicago and report to the commanding general, department of the Lakes for duty as chief surgeon of that department.

MATTHEWS, Major WILLARD S. H., surgeon, is honorably discharged from the service, to take effect November 30, his services being no longer required. Major Matthews will proceed to his home.

PINTO, A. S., acting assistant surgeon, leave of absence granted October 17 is further extended 10 days.

HEPBURN, JAMES H., acting assistant surgeon, is relieved from duty at the general hospital, Fort Bayard, and will proceed to Fort Caswell for duty, relieving Acting Assistant Surgeon Edwin I. Shores.

SHORES, EDWIN I., acting assistant surgeon, will proceed to San Francisco, Cal., and report to the commanding general, department of California for assignment to duty with troops destined for service in the Philippine Islands, and upon arrival at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

TENNEY, ELMER S., acting assistant surgeon, is granted leave of absence for 1 month and 15 days, to take effect upon his being relieved from duty at Fort Douglas.

BYRNE, Major CHAR. B., surgeon, is relieved from further duty in the department of Porto Rico, and will proceed to Fort Sam Houston for duty.

PINTO, ALVA S., acting assistant surgeon, is relieved from duty in Cuba, to take effect upon the expiration of his present leave of absence, and will proceed from Omaha, Neb., to San Francisco, Cal., and report to the commanding general, department of California, for assignment to duty with troops en route to the division of the Philippines, and upon arrival at Manila will report to the commanding general, division of the Philippines, for assignment to duty.

NEUGARDEN, Captain GEORGE J., is granted leave of absence for 2 months, on surgeon's certificate.

Changes in the Medical Corps of the U. S. Navy, for the week ended November 17, 1900.

WHITE, C. H., medical director, placed on the retired list of the Navy, from November 19, 1900, having reached the age of 62 years.

BLAKEMAN, R. S., passed assistant surgeon, detached from the "Pensacola," and ordered to the Naval Hospital, Mare Island, for treatment.

BETLEA, C. S., assistant surgeon, ordered to the "Independence."

McCLURG, W. A., surgeon, ordered to additional duty on the "Yankee."

GARTON, N. M., assistant surgeon, detached from the "Indiana," and ordered home to wait orders.

ALFORD, A. R., passed assistant surgeon, detached from the "Castine" and ordered to the "Culgoa."

JOHNSON, M. K., passed assistant surgeon, detached from the "Celtic" and ordered to the "Brutus."

CURL, H. C., assistant surgeon, detached from the "Culgoa" and ordered to the "Castine."

DAVIS, E., assistant surgeon, detached from the Cavite Naval Station and ordered to the "Brutus."

BELL, W. L., assistant surgeon, detached from duty at Guam and ordered to the "Celtic."

WRIGHT, B. L., assistant surgeon, detached from the Naval Hospital, Cavite, and ordered to the Naval Hospital, Yokohama, for treatment.

Changes in the U. S. Marine-Hospital Service, for the week ended November 15, 1900:

CARTER, H. R., surgeon, granted leave of absence for 15 days from November 16, on account of sickness. November 10.

STONER, J. B., passed assistant surgeon, to report at Washington, D. C., for special temporary duty. November 13.

GREENE, J. B., passed assistant surgeon, to proceed to Bremen, Germany, for special temporary duty. November 13.

MOXCRE, J. A., acting assistant surgeon, granted leave of absence for 30 days from December 15. November 14.

SCHLAAR, W. F., hospital steward, to report to Acting Director of Hygienic Laboratory for duty. November 9.

SCOTT, E. B., hospital steward, granted 1 day's extension of leave of absence. November 12.

MASON, M. R., hospital steward, to proceed to San Francisco, Cal., and report to the medical officer in command for duty and assignment to quarters. November 12.

RYDER, L. W., hospital steward, relieved from duty in the Hygienic Laboratory, and directed to report to the medical officer in command at Washington, D. C., for duty. November 9.

Board convened to meet at Washington, D. C., November 13, 1900, for the examination of Assistant Surgeon L. E. COFER, to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the board—Surgeon PRESTON H. BAILLACHE, chairman; Surgeon G. T. VAUGHAN; and Passed Assistant Surgeon H. D. GEDDINGS, recorder.

Menelik, Emperor of Ethiopia, has prohibited the use of tobacco in his dominions under severe penalties, and has been awarded the first prize by the French Society against the Abuse of Tobacco.

foreign News and Notes.

GREAT BRITAIN.

The University of London.—The second meeting of the new Senate was held November 7, and it is stated that the work of reorganization was proceeded with.

The Cost of the Plague in Glasgow.—According to a despatch from Glasgow the estimated cost to that city of the recent visitation of the bubonic plague was £1,000,000 (\$5,000,000).

Diphtheria has increased to such an extent among the pupils of the Birmingham Bluecoat School that the Governors have decided to close and disinfect the building. The cases are mild and progressing favorably.

Diphtheria.—More than 60 cases have been recently notified in the Newbridge area of the Abercarn District Council and the authorities have decided to close the board schools, which were only lately reopened after having been closed for the same cause.

Sir William Thomson, surgeon to the Richmond Surgical Hospital, Dublin, and chief surgeon to the Irish Hospital in South Africa, has been appointed by the Queen to be one of the surgeons in ordinary to Her Majesty in Ireland, in place of Sir William Stokes, deceased.

Catalepsy.—David Brown, a clerk of Yarrow, has been lying at the Newcastle Infirmary in a state of catalepsy, with the exception of a recent interval when he spoke a few words, since March 31. It was stated that he had been unconscious for 5 weeks previous to his removal to the infirmary.

"Liftman's Heart."—The *London News* sounds a note of warning to people with weak hearts on the danger of using elevators. The rapid transition from the heavier air at the foot to the more rarefied air at the top is regarded as very deleterious. Elevator boys have died suddenly and "liftman's heart" has been added to the roll of diseases.

Influenza in London.—There were 12 deaths reported in London from this disease last week, which is an increase over the two previous weeks. The disease has never been known to make a start there so early in the season. Last year the disease manifested itself first in December, which was earlier than the previous year, and a few weeks later the death-rate was as high as 350 a week.

Local Authorities and Vaccination.—On the appointment of a vaccination officer at King's Lynn the guardians adopted a resolution that he was only to prosecute on special instructions. The clerk ruled that they had no power to make this stipulation, but the chair then refused to sign the appointment without the addendum. The matter will have to be adjudicated upon by the Local Government Board authorities and the guardians may find that the authority of Parliament cannot thus be set aside with impunity.

Homes for the Poor in Dublin.—The corporation of this city has sanctioned the purchase and clearing of an area of 2½ acres composed of some of the most disreputable and unhealthy streets in Dublin on which will be built housing accommodation for about 2,000 of the very poor. The total cost of the scheme is estimated roughly at £50,000, and it is thought that even with the small rent of 2 shillings a week for a room in these new buildings the plan will not be a costly one to the rate-payers.

Milk Adulteration.—A Kensington dairyman detected in selling diluted milk, contended that he was exempt from penalty as he held a warranty of the purity of the milk from the farmer who sold it to him. Proceedings were then taken against the farmer, who insisted that the warranty which he had given only covered the article as long as it was in his custody. On this ground the summons was dismissed, as the magistrate held that if any one was legally responsible, it was the carrier. If this decision be right it will be necessary for dairymen to see that the warranty covers all the time

antecedent to the actual delivery to them, or else the railway companies will have to refuse to carry milk not so guaranteed.

Newcastle Infirmary.—At the last quarterly meeting of governors of the Royal Infirmary. Newcastle-upon-Tyne, the establishment of an out-patient department for mental diseases was discussed. A proposal had been forwarded by the honorary staff to the House committee recommending that there should be such a department, and also such alterations in the rules and statutes should take place as would allow of the appointment of one physician for the department of mental diseases. This was carried.

Proposed University for Newcastle.—Lord Barnard at the recent opening of the New Science Building of the Northeastern County School, at Barnard Castle, alluded to remarks made by Lord Grey at the opening of the Durham College of Science, Newcastle-upon-Tyne, concerning a university for Newcastle. It is well known that while the faculties of medicine and science are in Newcastle-upon-Tyne, and the work is carried on in the colleges that bear these names, the university is in Durham, distant 15 miles, and though for some reasons it is desirable to maintain the connection, the development of the Birmingham University has given occasion to Lord Grey and other distinguished men to ask themselves if the time has not come for Newcastle to have a university of its own.

The Title of Licentiates.—Since the resolution of the Court of Assistants of London was communicated to the medical journals, constant applications have been made by Licentiates in reference to the titles which they may adopt, and suggestions have been offered as to particular letters and signs descriptive of the qualification of L.S.A. 1886. By a further resolution of the Court of Assistants, it has been resolved that the only titles which the Society can authorize as a proper description of the qualification L.S.A. 1886 are those of physicians and surgeons, either added to the title of L.S.A. 1886 or used alone. And it was further resolved that the Society should discourage in every possible way the use of any other titles or letters on the ground of its tending to cause confusion and to destroy uniformity.

Proposed Sanatorium for the Tuberculous.—It is purposed to erect a sanatorium in Flintshire for the treatment of patients suffering from phthisis. The scheme owes its inception to Mr. W. J. Crossley, of Manchester, who, it is understood, will not only erect the buildings at his own cost, but will also endow them. The locality selected lies between Halkin and Rhydymwyn on the estate of the Duke of Westminster, near Moel Gaer, a commanding mountain. The scheme provides for the erection of a large central residential building for the patients and a number of small bungalows on the southwest slope of Moel Gaer, to which the patients will proceed in the daytime in order to gain the full benefit of the pure mountain air. It is also purposed to plant the place throughout with pine trees, another essential to the treatment of tuberculosis on the open air system.—[*Lancet*.]

An Action for Libel.—In June the English journals noted an action for libel which was brought by Agnes Dowling, a nurse, against Dr. L. F. Dods. The alleged libel was contained in a document purporting to be a certificate of lunacy and addressed to the local relieving officer. The defendant pleaded justification and privilege. The judges before whom the case was tried held that the occasion was privileged, but the jury found for the plaintiff, awarding her damages to the amount of £100. The plaintiff in her evidence showed herself to be the victim of dangerous hallucinations, so that the result of the trial surprised the medical profession and the public. November 6, before the Master of the Rolls, Lord Justice Collins and Lord Justice Stirling, an application was made by Dr. Dods for judgment or a new trial. Miss Dowling attempted to show that Dr. Dods had been actuated by malice, but the judges held that there was no evidence of malice, and judgment was entered for the defendant with costs.

The Use of Tobacco on Active Service.—The *Lancet* in an article on this subject calls attention to the fact that the soldiers in South Africa endured long marches and privations when there were only 2 or 3 biscuits a day without

grumbling if only the real physical content of each 24 hours, the pipe smoked by the smouldering embers of a camp-fire, were not denied them. It adds: It is difficult, then, to believe that tobacco is anything but a real help to men who are suffering long labors and receiving little food, and probably the way in which it helps is by quieting cerebration—and thus allowing more easily sleep, which is so all-important when semistarvation has to be endured. It would be profitable and interesting could medical officers have taken special note of the capacity for sleep previously evidenced by those who broke down and also of their indulgence or nonindulgence in tobacco.

Field Hospitals in War.—It is reported that Mr. Frederick Treves will soon publish a book upon ambulances, the subject-matter of which will have been gathered from his experiences in South Africa. In a paper read before a recent meeting of the British Medical Association he said that the South African campaign had shown the value of a large mobile field hospital (taking 300 to 600 patients), which should follow the colors and have its own transport. The recent campaign also demonstrated the fact that the field hospital was no place for a female nurse, but that they might be increased with advantage in the base hospitals. The orderly had to take the place of the nurse many times in these hospitals. He urged the formation of an army medical reserve by inducing recently qualified medical men to agree to serve for 3 years, 1 with the colors and 2 with the reserve. This reserve would be called upon only in time of war, and would enable the army medical department to avail itself of a body of specially trained medical men, who, from its point of view, would have the advantage of an army training. He was of the opinion that the services of men thus trained would be more valuable than those of a number of civilian surgeons chosen more or less irrespective of their qualifications.

Meat Inspection.—The report of Dr. Henry O'Neill to the Markets Committee of the county borough of Belfast contains much of interest on these subjects. This gentleman represented the corporation of Belfast at the Congress of Hygiene and Demography held in Paris last August and devoted several pages to the inspection of meat in Paris, where all animals intended for food must be slaughtered at the public abattoirs at La Villette, Grenelle Vaugirard, or Villejuif. The meat is examined by qualified inspectors under the superintendence of a veterinary surgeon, and if it proves to be good it is stamped with the letters "P. P.," meaning Prefecture of Police. Meat obtained from animals slaughtered outside the city can only obtain entrance through the appointed city toll-gates and must be taken to the public slaughter-houses or to certain specified markets, to receive the stamp if satisfactory. Meat improperly admitted for human food is seized and either destroyed at the owner's expense, or if claimed for use in manufacturing purposes it is subjected to proper treatment before it is restored. In Berlin the method is similar, and all meat slaughtered in the country or abroad and intended for human consumption in the city must be brought to the public abattoir and meat market for inspection and receive the official stamp. In London there is no regular inspection of meat except in the market at Smithfield, and all meat is considered fit for food unless it has been condemned by the sanitary authorities. It is therefore probable that London receives diseased meat from all parts of the country. Dr. Neill suggests improved methods of inspection. In a separate report presented to the Public Health Committee of the county borough of Belfast he mentions the method of milk-inspection followed in Manchester and discusses the question of the municipal supply of sterilized milk as practised at St. Helens in Lancashire for more than a year.

CONTINENTAL EUROPE.

Bunsen Library.—The library of the great chemist, Bunsen, is now being sold at Leipsic.

Smallpox in Paris.—An epidemic of smallpox has broken out in Paris, due probably to the massing there of Arabs and other people from the East during the exhibition. Notices have been posted by the police warning persons who have not been vaccinated within 6 years to be vaccinated now.

The University of Buda-Pesth has recently conferred the degree of Doctor of Medicine on Fräulein Charlotte Steinberger, the first female physician in Hungary.

King Oscar, of Sweden, is reported in a very low state of health. His recent brain attack, it is said, deprived him of his memory and he seems unable to recuperate. The King has been in bad health for some time past and his eldest son and heir, the Crown Prince Gustaf, formally resumed the regency last month.

The Russian Red Cross Society.—The Russian government has again imposed a special tax for the benefit of the Red Cross Society. The first was a tax of from 5 to 10 rubles upon licenses to travel abroad, and now railroad tickets are taxed 5 kopecks when the fare is 2 rubles or upward. It is estimated that the ticket tax will yield \$125,000 per year and that on licenses \$100,000. It is understood that the Czarina, whose interest on the Red Cross Society is keen, originated the idea of imposing the taxes.

MISCELLANY.

A Tax on Childless Frenchmen.—A bill has been introduced into the French Senate, says the *Medical Record*, providing for a tax on celibates of both sexes after they reach the age of 30, and upon childless couples who have been married for 5 years, the tax to be maintained until a child is born to them. The aim of the bill is, of course, to provide a remedy for the threatening depopulation of France, by increasing the birth-rate.

Obituary.—DAVID YOUNG, at Ventnor, Isle of Wight, October 18, aged 61.—JOHN TILSLEY, of Bath, October 28, aged 32.—ALFRED WILLIAM HUGHES, professor of anatomy, King's College, London. He was one of the pioneers and the organizing secretary of the Welsh Hospital, South Africa.—EUGENE JANSSENS, of Brussels, aged 69.—GOTTHARD BÜLAU, of Hamburg, aged 65.—J. L. SHERLOCK killed, in the fighting in the Uganda Protectorate, October 13.

Epidemic Menaces Peking.—Sanitary conditions in Peking are reported serious. Since the foreign occupation many Chinese have died of smallpox and other infectious diseases. Fearing that their funerals would be interfered with, they have kept most of the coffins containing their dead in their houses and courtyards. The question of removing garbage has become one of grave importance. As the natives are forbidden to deposit refuse in the streets, there is now an enormous accumulation in their dwellings and yards, which threatens a serious epidemic. In view of the large number of troops in and near the capital, the consequences of such an outbreak would be serious. Smallpox, which is always prevalent, is much more malignant during the winter season.

The South German Society of Neurologists and Alienists held their latest session recently in Baden-Baden. One of the most important addresses made was that by Professor A. Hoche, of Strassburg, on "Shakespeare and Psychiatry." The substance of his theme was that the treatment of problems in belles-lettres by medical authors has recently been discredited almost urgently—not without the fault of the latter, by the way; and that the claim that the scientific treatment of such problems is impossible is a prejudice. In the formation of characters who were really diseased in mind, Dr. Hoche thinks that Shakespeare distinguishes himself from other poets advantageously; he has not lapsed into the error or arbitrary production of such figures of psychiatric illness as makes the views of many poets regarding such a condition unendurable to the expert. Numerous little traits prove to the specialist that Shakespeare must have had for his work models taken from the daily life around him. Later poets, with very rare exceptions, share the current errors of the laity in regard to the nature of mental aberration; the influence of their mistake on the great majority is therefore serious enough. The attempt made by Ibsen, in "Ghosts," to demonstrate in a paralytic the problem of hereditary transmission was, he says, unhappy and unsuccessful; his suppositions were false and the paralytic as a figure was badly drawn.

2.—Sawyer says that a good way to acquire **ambidexterity** is to learn sinistral handwriting with pen and ink. He says that ambidexterity in the medical profession is a great acquirement, especially in laryngoscopy and ophthalmoscopy, in palpation, in percussion and in examination per vias naturales. [G.B.W.]

3.—The practical teaching which the present state of knowledge on the **diagnosis of diphtheria** seems to admit is apparently somewhat as follows: (1) Diagnosticians should at once regard and treat, without waiting for a bacteriologic report, all cases as diphtheria, in which the clinical signs and symptoms are such as would have raised but little or no doubt in their minds as to their nature in the days before the coming of the bacillus; (2) they should also regard and treat as diphtheria all cases which, although lacking the usual clinical "stigmata," are shown by bacteriologic examination to be associated with bacilli whose products kill animals and cause the characteristic lesions; albeit even here they may be in error, though on the better side; (3) the mere presence of bacilli "morphologically indistinguishable" from the pure "diphtheria bacillus," the host being healthy and inoculation results negative, may probably be ignored in practice, and so also may all negative bacteriologic reports in cases where there are any clinically recognized symptoms or signs of the concrete disease. Donkin believes that the diagnosis is best made after careful clinical observation. [J.M.S.]

4.—**Myelopathic albumosuria** may be defined as a disease characterized by an invasion of the cancellous tissue of the bones of the trunk by a cellular growth, by a disappearance of the osseous tissue, and by the presence in the urine of large quantities of a peculiar albuminous substance belonging to the class of bodies known as albumoses. The morbid anatomy of the disease consists in a remarkable change in the ribs, sternum, and the bodies of the vertebrae. The hard substance is reduced often to a mere shell, which breaks on the slightest pressure with the fingers; the cancellous tissue has almost entirely disappeared; and spontaneous fractures of the ribs are common. The interior of the bone is occupied by a reddish, gelatinous, greasy mass, somewhat like splenic pulp, that can readily be squeezed out by pressure on the thin and brittle bone. Microscopically, it consists of a vascular mass of cells round or spindle-shaped,

and in some cases islets of cartilage have been found. The whole structure resembles sarcoma, and the condition is generally known as "multiple myeloma." The disease is one occurring in the second half of life, and is apparently more frequent in men than in women. The symptoms may be classified under two heads: those connected with the affection of the bones, and those connected with the condition of the urine. The first complaint is generally of pain in the lumbar region suggesting lumbago; it is generally aggravated by movement; the patient probably looks anemic, the pains do not yield to treatment; but there is nothing to suggest the serious nature of the case unless the condition of the urine is recognized. In spite of the pain, weakness, and deformity, the patient is able to leave his bed and walk about until near the end of the case—a circumstance which is evidently due to the fact that the disease does not attack the bones of the extremities. In this respect it differs in a striking manner from osteomalacia, with which it has been sometimes confounded, in which the long bones are early affected, and the power of standing is lost almost from the first. The characteristic feature of the urine is the presence therein of a proteid which bears a superficial resemblance to albumin, but which can be easily shown to differ from albumin in several of its reactions. The characteristic reactions of the body are the following: 1. It coagulates at a comparatively low temperature ($60^{\circ}\text{C.} = 140^{\circ}\text{F.}$). 2. The coagulum is redissolved on boiling. 3. It is readily precipitated by hydrochloric acid, as well as by nitric acid, and the precipitates are dissolved on boiling. The condition of the urine appears to be pathognomonic of the disease. In the early stages the disease may be mistaken for muscular rheumatism; when deformities appear it may be mistaken for osteomalacia or for tuberculous disease of the spine. On the other hand, the condition of the urine might lead to the diagnosis of large white kidney being made, or, if the albumose is spontaneously coagulated, to that of chyluria. The disease seems to be always fatal, but sometimes its course is remarkably prolonged. No treatment which has been tried hitherto has appeared to have the slightest effect on the progress of the disease. [J.M.S.]

5.—Ruffer and Crendiropuolo found it necessary to invent a method by which the **diffusible products of the life of microorganisms** could be obtained without subjecting the microorganisms themselves, or the culture media, to the action of heat, filtration, or chemical reagents. The apparatus consists of an ordinary test-tube filled to any required level with bouillon or some other fluid cultivating medium, and plugged with cotton-wool. Through this plug another smaller glass tube is introduced, to the lower extremity of which is attached a collodion sack. This inner tube is filled to any required level with some cultivating fluid and is plugged at the upper extremity with cotton-wool. The collodion bags are prepared as follows: A small test-tube is rapidly dipped, bottom downward, into a small tumbler filled with collodion, until 2 or 3 inches of the tube are covered with collodion. It is then withdrawn and allowed to dry bottom upward. After drying, the same process is repeated 2 or 3 times. The collodion is then found to stick tightly to the glass tube. In order to separate the collodion from the glass tube, the whole is dipped alternately for a few seconds in strong spirit and then into water. The water and spirit diffusing through the collodion gradually loosen it from the glass. After a few minutes the collodion bag can easily be peeled off from the glass tube. A small glass tube of such a size that it can just enter is then introduced into the open extremity of the collodion bag, and the whole is then placed in the incubator at 37°C. The collodion bag now shrinks and tightly fits on the glass tube. All other methods of fastening the collodion bag have proved faulty in the hands of the authors as the fastenings invariably allowed microorganisms to get through. In order to sterilize the collodion glass tube, it is fixed in an empty test-tube, and the whole is sterilized at 150°C. by dry heat on one or several occasions. When this has been done the inner tube together with the plug are transferred aseptically to a tube of sterilized bouillon or gelatin of equal size, the plug now serving to close the tube of bouillon into which the inner tube is dipped. The bouillon in the inner tube is now inoculated with the microorganism to be studied, and the whole placed in the incubator. It is clear that this method may be used for a variety of purposes, as, for instance, the study of those products of the life of microorganisms that dialyse through a

collodion membrane. By filling the outer tube with therapeutic serum, for example, antidiphtheric serum, and the inner tube with a diphtheria culture, the action of serum on the dialysable products of the diphtheria bacillus may be studied; and inversely, the action of dialysable constituents of therapeutic serum on *Bacillus diphtheriae* and on its toxins. By inoculating the liquid contained in the outer tube with one kind of microorganism, and that of the inner with another, the antagonism between the two may also be studied. [J M S]

6.—Grassie and Noe have demonstrated that when *anopheles* bites the *larvas of filariae* come out of the labium, and are thus inoculated in the bitten animal. The mechanism of exit represents one of the most singular and admirable phenomena that one can imagine for the diffusion of parasites. As is known, the *Culicidae* introduce only 6 of the 9 appendages that constitute their mouth apparatus. Of these, 2 form 2 canals, a wide canal constituted by the superposition of the labium to the hypopharynx, the other narrow, grooved along the hypopharynx itself. The wider canal serves very likely at the beginning of the puncture to emit some gases enclosed in the 3 sacs annexed to the anterior intestine (which, as we know now, have certainly a sucking function); later it serves for the passage of the blood; the narrow canal serves for the emission of saliva; the 4 stylets (mandibles and maxillae) cut with a saw movement. Of the remaining 3 pieces that constitute the mouth apparatus, the 2 palps during the puncture remain raised. When the mosquito proceeds to penetrate the skin the labium, as Reamur admirably described, buckles up at first toward the base, forming an ob'use angle. As the stylets gradually penetrate, this angle is advanced toward the middle of the labium, becoming extremely acute, so much so that when complete penetration is effected the labium appears doubled up on itself, forming a narrow kind of loop, and thus forms, through the conformation of the parts which close together, a new canal. The halves of the olive and the little tongue, resting against the skin of the animal which is punctured, embrace the 6 pieces penetrating the skin. It is certainly through the bending of the labium stuffed with filariae that the rupture of the integuments of the labium is brought about; along the dorsal groove and through the rupture thus produced the filariae come out to penetrate the body of their definitive host. In some cases the authors believe that they have positively found the rupture in the middle of the length of the labium in correspondence with the loop. It seemed to them also that the 2 halves of the olive and the little tongue, being in the above mentioned position, had an importance in directing the movements of the filariae toward the wound made by the stylets. Perhaps also the gases emitted in the first moment of the bite help the entry of the filariae into the body of the definitive host. However, it is certain that up to now all the *anopheles* that have punctured seemed free of the filariae they had previously carried in their probosces. [J M S.]

7.—Grunbaum calls attention to the use of **suprarenal gland extract** as a hemostatic in hematemesis. Suprarenal extract, when given for hemorrhage of the stomach, should be given in small doses, repeated at short intervals, for only while the vessel wall is under the action of the extract will it remain contracted. The drug does not tend to coagulate the blood, as do the iron preparations. The sterile extract is not irritating, and may be used to wash out the bladder when bleeding occurs in that organ, also as a douche in postpartum hemorrhage. [G B W.]

8.—After a study of the **reduction of temperature by quinin**, Sykes concludes: 1. That quinin is absorbed rapidly, although only given as a powder suspended in milk. In the first series of observations, the temperature began to fall within 49 minutes; in the second series within 20 minutes; and in the third series within 22 minutes. 2. That the size of the dose, within certain limits, does not seem to affect the rapidity of the defervescence. 3. That the antipyretic effects of the quinin are probably due to the production of diaphoresis. [J M S.]

10.—Godson, as the result of a collective investigation found that in the **treatment of whooping-cough** the drugs commonly employed and chiefly depended upon were antipyrin, belladonna, bromids, carbolic acid, creosote, and opium, while as accessory and occasionally useful drugs chloral hydrate, quinin, and butyl-chloral-hydrate were

mentioned. The antispasmodics are always combined with expectorants, of which the alkalies are the greatest favorites. Inhalants appear to be in general use, the ones referred to being carbolic acid, creosote, bromoform, and chloroform. None of the answers that were received were enthusiastic except from those who had used creosote. The simplest and best method of administration is to sprinkle the drug on a cloth, and hang the cloth in the sickroom or nursery to dry. The method of treatment that the author has found most satisfactory is the following: Commence at once with the continuous inhalation of creosote. Clear the lungs of bronchitis as much as possible before using any special internal antispasmodic remedies. In bronchopneumonia, however, belladonna appears at once to do good. In all cases, if or when the chest is fairly clear, and the circulation is good, antipyrin may be given in suitable doses. Expectorants should be combined with the antipyrin. Good air, warm clothing, sunlight, and wholesome food are necessary in all cases. [J M S.]

11.—In this case of **abdominal injury caused by the horn of rhinoceros**, a portion of several knuckles of gut protruded through the opening, which was about 6 inches in length and about 2 inches above Poupart's ligament. The gut was thoroughly cleansed and returned to the abdominal cavity. The parietal peritoneum was then drawn together by sutures; the muscles united by another set of sutures, and the skin and superficial fascia by still a third set. The patient made complete recovery, and in 11 days was up and around and desired to go back to his duty as a soldier. [G B W.]

12.—Somers reports a case of **scarlet fever complicated by a pemphigoid eruption**. [J M S.]

13.—Death in this case occurred about 18½ hours after the first symptoms of **perforation of the gastric ulcer** were noticed. No attempt at operative relief was undertaken. [G B W.]

14.—In attempting to remove a mass of cerumen from the right ear, in a patient who was partially deaf as a result of the mass of pus, a **slate pencil** ¾ of an inch long came out. It had lain in the ear for 25 years, causing no pain, but considerable deafness from the accumulation of cerumen. [G B W.]

15.—Nott reports the case of a boy, aged 13 years, who had been **stung by a wasp** on the under surface of the tip of the tongue. He was in great pain and salivating profusely. The tongue was greatly swollen, hard, tender, and rounded in shape. The frenum was tightly stretched, and the tongue protruded nearly an inch beyond the teeth. A quarter of an hour later the organ had become still more swollen and was quite immobile. Any attempt at movement produced pain in the floor of the mouth and in the neck. In the meantime the saliva ran away in astonishing quantities. The submaxillary glands were swollen and tender, and the widely-distended lingual ducts could be seen pouring out their secretion. In an hour and a half some movement had returned and the organ had become less tense. The salivation continued throughout the night, but the swelling rapidly subsided. There is little doubt that had the insect flown far enough into the mouth to sting the soft palate, the boy's life would have been in danger in a very few moments. The enormous activity of the salivary glands was the chief feature of the case. As pain seemed the severest symptom requiring treatment, the tongue and mucous membrane of the mouth were brushed with a strong solution of carbolic acid, with the greatest relief to the sufferer. There were apparently no remote toxic symptoms; the pallor and faintness were possibly due to fright. [J M S.]

16.—Dick reports the case of an adult who recovered after taking one ounce of liquor strychninae hydrochloratis (British Pharmacopeia). This amount contained 4½ grains of the salt, and represented 5.29 milligrams per kilogram of body weight. [J M S.]

17.—Wiggins reports a case of **ulcerative endocarditis** that terminated fatally from **rupture of the heart**. The history indicates that the patient lived 3 days after rupture occurred. [J M S.]

18.—This case of **carcinoma** is of interest only in showing the discouraging results from injections of either yeast-culture or Coley's fluid. Neither of these had any perceptible effect in stopping the progressive growth of the tumor. [G B W.]

1.—Maylard gives the results of 15 months' experience in the **surgery of the stomach**, reporting all cases upon which he has operated during this period. He first calls attention to the common erroneous impression given by many textbooks as to the true position of the stomach. The cardiac orifice is not, as generally depicted, slightly above the pyloric orifice, but considerably above it, and the lesser curvature instead of looking upward is directed toward the right. Four-fifths or more of the viscus is to the left of the middle line; the cardiac orifice is situated about opposite the junction of the seventh costal cartilage with the sternum, the pylorus 2 or 3 inches below the ensiform cartilage and an inch to an inch and a half left of the median line. The erroneous idea of a transverse position has doubtless arisen from the conditions found in the dissecting room and necropsies with the relaxation of the diaphragm, and general loss of support which changes the normal relations of the organ. Maynard believes that exploratory gastrotomy is a simple and safe measure which will afford relief and effect cure in many cases in which the patient has been lavaged, physicked and ordered a change of air and scene for some organic obstruction of the pylorus. He has performed this operation twice during the time mentioned and in the first case found a tumor of the epigastrium too far advanced for removal. The patient was relieved, however, by gastrojejunostomy. In a second case the pylorus was contracted from the cicatrix of an old healed ulcer and the patient was relieved. The Kader-Senn operation he has performed 4 times, and he considers that it has some advantages over the Frank method. He has also performed the operation of gastrorrhaphy with a satisfactory result and maintains that the operation is a justifiable one. Some of the results have been strikingly successful. Maylard is unwilling to express any judgment on the merits or demerits of gastrectomy for extensive disease of the stomach. However, he considers the operation a very severe one, of extreme gravity, and the doubtful nature of the result should be well weighed with other considerations when the operation is thought of. He has performed gastrolisis in one case for the relief of adhesions between the pylorus and the under surface of the liver resulting from an old healed ulcer. He believes that gastrolisis will relieve and cure various cases which have hitherto been vague in their symptoms and intractable to all forms of medical treatment. Gastrojejunostomy is considered a compara-

tively simple and safe operation, and it is replacing such operations as pyloroplasty and pylorotomy for cicatricial contraction of the pylorus. It is no doubt also of value in certain cases of gastric ulcer. Maylard reports 6 cases in which he has performed this operation: for cicatricial contraction of the pylorus, in 1 case with a fatal result; for the relief of inseparable adhesion to the liver in consequence of chronic ulcer in another case; for the relief of obstruction due to carcinoma of the pylorus in 3 cases; and for carcinoma of the body of the stomach in 1 case. [M.B.T.]

2.—DeLépine gives a brief summary of the **early history of bacteriology**. He also calls attention to the growth in recent years of laboratory diagnosis in England, and gives some statistics of the work done in the laboratory of Owen's College, Manchester. [J.S.]

3.—To be treated editorially.

4.—Chalmers states that **estivoautumnal fever** is the most common type of malaria among Europeans on the Gold Coast. Predisposing causes are chills, constipation, mental worry, excesses, organic disease, improper food, and exposure to the sun. Infection takes place through the mosquito, particularly through a new species, the *Anopheles kumasi* of which he gives a description. The parasites found in the blood are usually nonpigmented, however the pigmented specimens are also quite common. The fever is frequently quotidian. With this type there is enlargement of the spleen and liver. Prognosis is good. Treatment consists of aperients, diaphoretics, cold applications often slightly acid, and quinin in 10 or 15 grain doses twice a day, and during convalescence iron is employed. Prophylaxis consists in airy, comfortable dwellings, mosquito nets, and occasional doses of quinin. [J.S.]

5.—Waldham records a number of cases of **aneurysm** in which the **diagnosis was made** or confirmed by the **x-rays**. In the first case the aneurysm was not at first detected, although it was suspected. The picture showed an enlargement at the left base which subsequently increased considerably in size. It was not certain, however, just where the aneurysm arose. The second patient had a huge tumor almost filling the right side of the chest. Under appropriate treatment the symptoms improved and the size of the tumor was considerably less in a subsequent skiagram. [J.S.]

6.—Duncan records an interesting series of **infantile deformities** apparently the result of **maternal impressions**. The first case was that of a child born with a hand from which all the fingers, excepting the thumb and little finger, were lacking. The mother had been very much worried by a photograph of her husband in which this deformity appeared to exist. The husband's hand, however, was, as a matter of fact, normal. Another woman, who saw this child, was subsequently delivered of an infant whose hands and feet were deformed. Duncan quotes other cases from literature. [J.S.]

7.—Morton reports the case of a man who was killed by an explosion of a detonating signal which he held in his hand. This was filled with **tonite** and was capable of blasting rock for the distance of a yard. There were a number of serious wounds in the body; perhaps the most interesting being one in the left lung. As a result of old pleural adhesions the lung did not retract, and this possibly explains the ability of the patient to walk several yards before falling down dead. A curious feature of all the wounds was the **apparent disintegration of all the soft parts**. [J.S.]

8.—Clark reports the case of a girl of 11, who had been in an asylum for 3 years because of idiocy and boisterous behavior. On examination he found a **depression of the skull** in the left occipital bone near the parietooccipital suture and about 2 fingers' breadth from the middle line. It was about 1½ inches long and ¾ inch wide. The depression resulted from a fall when the child was 4 years old. Recovery had been apparently uneventful, but after about a week she was subject to severe convulsions preceded by spasm of the right leg and arm, and the mental faculties remained stationary. **Trephining** was performed, and the meninges were found enormously thickened and adherent. The dura was opened and adhesions were separated. The disc of bone was not replaced and the scalp wound was completely closed by sutures. Uninterrupted recovery followed with steady improvement in every way. Convulsions have not

returned since the operation, and the child's mental condition has considerably improved. Only 2 months had elapsed at the time of report, however. [M.B.T.]

9.—Brandt believes that in all cases of **rheumatism** an excessive excretion of uric acid in the urine can be demonstrated. This can be corrected by the administration, in sufficient quantities, of alkaline mineral waters, and by suitable hygienic measures. The latter are carried out more satisfactorily at a sanatorium than at the patient's home. The treatment should be continued until the uric acid returns to its normal quantity. [J.S.]

11.—Hibbs reports operations on 5 patients for **talipes equinovarus** by a new method of lengthening the tendo Achillis. He secures lengthening by transverse incision and longitudinal incision, thus preserving the continuity of the tendon. [The method does not differ essentially from a similar method that has been performed for several years and was, we believe, first suggested by Keen. M.B.T.]

12.—Harding reports a case of **impetigo** occurring 8 days after vaccination. The vaccination wound had been chafed by a dirty shirt, which sufficiently explains the infection. The organism present was *Staphylococcus pyogenes aureus*. [J.S.]

13.—Springthorpe reports a case of **paralysis of the perineal muscles following typhoid fever**. The patient had worn a puttee very tightly during the campaign in South Africa, and it is suggested that this pressed upon the anterior tibial nerve, as it wound about the head of the fibula. The toxin of typhoid should be regarded as the exciting cause. [J.S.]

14.—A woman, 28 years old, while filling a paraffin stove, caught fire, causing extensive **burns** of the **entire right upper extremity** so that a granulating surface extended into the right axillary and mammary regions. Ineffectual attempts were made to cover the surface by skin grafting, but it was evident that the hand was useless because of the involvement of the muscles. **Interscapulothoracic amputation** was performed, the clavicle was sawed across in its outer half, the vessels were tied with silk and the flaps were shaped so as to save as much skin in the region of the burn as possible. Bleeding vessels were secured as they appeared. The patient was much collapsed after the operation, but responded to an intravenous injection of a quart of hot saline solution. Rapid recovery followed and she is now in good health. [M.B.T.]

15.—A girl of 11 years had been ill 3 weeks with vomiting and diarrhea and an elevated temperature. The spleen was enlarged, but the Widal reaction was negative. After entering the hospital the child's temperature fell by lysis, but later physical signs appeared which were thought to indicate double pneumonia at both bases. Exploratory puncture later on demonstrated **empyema** of the right pleural cavity, which was evacuated after excision of a rib. The patient had had considerable abdominal pain previous to the operation which was thought to be of pleuritic origin. There was considerable fulness and hardness of the abdomen, but a resonant note everywhere on percussion. As the abdominal pain continued, exploratory incision was made, and on reaching the posterior surface of the rectus abdominis thick yellow pus escaped which had burrowed between the fascia transversalis and the abdominal wall; 37 ounces of pus was evacuated. The patient began to improve soon afterward and left the hospital about 2 months from the time of entrance. [M.B.T.]

16.—A girl of 3 years swallowed a brass shawl-pin, which ulcerated through the intestine into the abdominal wall, and it was removed by incision. In a second case abscess of the neck resulted from swallowing the husk of an oat, which was discharged through the tissues of the neck after incision. [M.B.T.]

New York Medical Journal.

2.—Brandt believes that the origin of endothelioma is not at all settled, although those arising from the bloodvessels are considerably more rapid in their growth and have more frequent metastases. Usually there is a history of trauma, and the result of this irritation starts a proliferation of the capillaries, and this in turn the endothelium. It is hard to tell if these are really bloodvessels or blood spaces, and as the walls are so thin, parts of this tissue are broken off in the circulation and are carried to other places like other emboli, and start new nodules wherever they happen to lodge. Endothelioma occur more frequently past middle life, with a preponderance to the male sex. [W.S.N.]

5.—See page 972, this issue.

6.—Douglas believes that patients suffering from **delirium tremens** should be put to sleep soon after their arrival in the hospital. This can be done with apomorphin in a few minutes without danger and without emesis. Such patients should not be restrained by physical force. Whisky or alcohol in some other form should be prescribed, because sudden withdrawal aggravates the disease and frequently causes it. The patient should be nourished with milk, egg-nog, or some other liquid food. [J.M.S.]

8. Ptomain-Poisoning from Eating Cheese. G. LEO HAGEN BURGER.

1.—Brewer in his study of differential diagnosis in diseases of the gallbladder and ducts, divides them into 3 classes: (1) Calculous; (2) inflammatory; (3) new growths; this excludes actinomycosis, tuberculosis, and gumma. He thinks this is a better one than Kerr's, which is largely clinical. Under (1) we have stone in a healthy gallbladder, cystic duct free; (2) stone in a previously inflamed gallbladder, duct free, adhesions; subacute cholecystitis, without stone; acute cholecystitis with stone; acute cholecystitis in contracted gallbladder, duct closed; hydrops of the gallbladder; empyema of gallbladder, stone in cystic duct; carcinoma of gallbladder; stone in common duct, acute obstruction; stone in upper segment of common duct, chronic obstruction; stone in common duct near papilla; and obstruction of common duct from pressure of tumor of other organs. The 3 symptoms most important are pain, jaundice, and tumor. Repeated attacks of paroxysmal pain in upper quadrant of abdomen, apt to occur at night or after fasting, accompanied by fever; more probable if pain radiates to the back and shoulder, with tenderness under border of ribs, and an elastic tumor with a slight lateral pendulum movement during respiration, suggests cholecystitis; no tumor indicates lesion of the common duct. Diseases that confound the diagnosis are gastric ulcer, appendicitis, renal colic, gastric crisis of tabes, inflammatory conditions of pylorus and duodenum, chronic obstruction, and syphilitic hepatitis. Tumor without pain or fever may suggest hydrops of the bladder; with jaundice and distention, pressure on the common duct; with fever and tenderness, empyema. The nodules from cancer may confound the diagnosis. Jaundice without symptom, catarrhal obstruc-

tion; temporary, with colic, a stone passing through the common duct; intermittent with colic, a floating stone in the common duct; continued pain with chills, fever, hepatic enlargement, tenderness and sepsis, infective cholangitis; with progressive enlargement of liver, previous colic, impacted stone near papilla. These symptoms without pain or fever and with a tumor, suggest pressure from a new growth on the common duct. In a series of 100 cases of growths (mostly carcinoma) of the bladder, 17 were males, and 83 females; $\frac{3}{4}$ of these were subjects of cholelithiasis. Carcinoma of the gallbladder was diagnosed in only 4 of this series. In 53 death occurred within 9 months. Eight autopsies on cases of acute biliary colic showed the stone in the common duct in 6; in the bladder in one; and the stones were scattered through the biliary passages in one. [W.S.N.]

2.—Stern gives a series of tables which he has constructed from the records of the city of New York concerning the mortality from diabetes mellitus. He found that the number of deaths is lower in summer than at any time of the year, highest of all in the fall, and next in the spring. The number, however, did not vary greatly. The largest number of deaths took place between the fifty-fifth and sixty-fifth years. There were but 10 deaths recorded in persons under 25. The whole number of deaths in males was 102; in females 100. The greatest number of deaths occurred in Germans, among which nationality there were 57. Next came the natives of the United States, 51; next the Irish, 37. The high mortality of Germans is considered to be due to the large number of Jews among these people. So far as could be learned a total of about 54 deaths, that is, about 25%, occurred in Jews, and about the same mortality occurred in those of Irish origin or descent. Fatal coma occurred 60 times, but it was impossible in many of these cases to say whether the coma was true diabetic coma or not; 43% of the recorded deaths in Hebrews were due to coma. In 9 instances in which the duration of the disease preceding the coma is reported, it was found to be 4 years and 5 months. The average duration of the coma before death in 9 instances in which it was reported was 44 hours. Extensive tables are given, but as Stern remarks, mortality records are very unsatisfactory as a means of formulating statistics, as the records are very incomplete. They are certainly also extremely untrustworthy, and it seems impossible to acquire much valuable knowledge by a study of them. [D.L.E.]

3.—Floersheim reports astonishingly good results from the use of **suprarenal powder** given in 3-grain doses, in acute or chronic bronchitis, bronchiectasis, bronchial asthma, when accompanied by hyperemia of the bronchial mucous membrane, congestion of the lungs, edema of the lungs, hemoptysis, and any pulmonary tuberculosis. He directs that the powder be first chewed without water, and then swallowed. In some of the acute cases the results were said to be permanent, while in most cases it was but temporary. It is said to have influenced cough or other symptoms in from 2 to 15 minutes. [Certainly a rapid action! D.L.E.]

5.—The case reported was that of a child of 2. The amount of **carbolic acid** taken was unknown. Treatment was undertaken, consisting of the use of a solution of magnesium sulfate and brandy through a stomach-tube, and traction of the tongue to aid respiration. There was some croupy respiration, but while intubation was thought of, it was unnecessary. The child vomited afterward and the vomit contained but little carbolic acid, hence the symptoms seemed to be the result of partial asphyxia from the local action upon the tongue and epiglottis and not the result of systemic poisoning. [D.L.E.]

6.—The patient was a man of 34, who had edema of the lower extremities and abdomen beginning in the left leg. No treatment was effectual, and a diagnosis of **chylous ascites** was not made until a month before death, when he was first tapped. The fluid removed had the appearance of rich milk. No cause could be determined. The patient had never left the United States excepting to go to the Klondike. [D.L.E.]

7.—The case was that of a man of 44, who had **universal rheumatoid arthritis** which had begun when he was 21. For 13 years he had been bedfast. The disease seemed to have involved practically every joint in the body, even the jaw and the vertebrae. It was necessary to remove some teeth in order to feed him. [D.L.E.]

8.—Two boys were seen for an attack of **abdominal**

cramp, vomiting and prostration, with fever. The whole family had eaten cheese, but these boys were the only ones who showed any disturbance. Both recovered within a few days. Mineral poisons were absent from the discharges, but there was a large amount of fatty acid present. When the cheese was given to kittens and dogs, however, it made the kittens seriously ill, and one dog had severe gastrointestinal disturbance with paralysis of the posterior extremity. Lead was absent, but there was some evidence of the presence of an **alkaloid in the cheese** which precipitated with platinum chlorid. [D.L.E.]

1. The Surgical Importance of Jaundice. ARCHIBALD MACLAREN.
2. The Hydratic Treatment of Tuberculosis. J. H. KELLOGG.
3. Pernicious Anemia: Report of a Case. G. R. TROWBRIDGE.
4. Some Observations on Affections of the Gallbladder. FRANK LE MOYNE HUPP.

1.—Maclaren in an article on the **surgical importance of jaundice** concludes that slight attacks of jaundice are of comparatively little importance, and that the majority of surgical diseases of the biliary passages have no jaundice at all. Persistent jaundice especially if progressive is usually a contraindication to operation, on the other hand intermittent, deep jaundice, especially if associated with chills and a rise of temperature, denotes a stone in the common duct which urgently demands removal. In 13 operations no disease was found in 2, adhesions of the gallbladder and pylorus was found in 1, and in 10, stones were found; all showed evidence of cholecystitis, yet none suffered from jaundice. He mentions a case in which all symptoms pointed to disease of the liver, but when the operation was performed, the organ was found normal, and the trouble due to a large postcecal appendiceal abcess. This patient suffered from jaundice, pain, etc. The stools were examined, but no stone was found. The patient died of shock, the postmortem confirmed operation. In cases of abcess of the liver the greatest difficulty is to secure proper drainage, and this is still more serious when it is on the upper surface. [W.S.N.]

2.—Kellogg continues his article upon the **treatment of tuberculosis with cold water**. He gives certain general rules that must be observed in all cases. First: Applications should not be made when the patient feels chilly, nor to the entire surface, unless the patient has been gradually inured to them. The duration, temperature, etc., must be adapted to each individual patient, in order to secure good reaction and to stimulate metabolism. For lowering temperature, only the mildest measures can be employed, otherwise chills are produced. If in the course of treatment there is loss of weight and strength, or aggravation of any of the symptoms, the treatment should be modified. The results that may be expected are favorable; the symptoms are alleviated, life is prolonged, and the patient made far more comfortable. He recommends the following methods for particular symptoms: For cough, sipping of hot water; to promote expectoration, drinking of considerable quantities of hot water, and at the same time the chest may be rubbed and the chest-bag applied and even worn all day. This often produces instantaneous relief. The pain may be relieved by a warm compress; hemorrhage, by hot applications to the extremities and cold applications to the chest; dyspnea, by hot applications to the spine; irritation of the throat, by the throat-bag, which may be worn night and day. Chilliness is treated by hot applications and a dry pack-bag; fever, by a neutral bath of from 92 to 95° F. for an hour; night-sweats, by sponging the surface with hot water at bedtime; cardiac disturbances, by a cold precordial compress; digestive disturbances, by a careful diet, including, in some cases, predigested foods, and by cold bathing; vomiting, by a cold compress to the abdomen and chest; diarrhea, by hot fomentations to the abdomen. The results of this treatment at the Boulder Sanitarium show that of 240 cases, 160 have been cured or more or less permanently improved, and the remaining 80 relieved. Kellogg makes a startling assertion that the general adaptation of hydratic treatment "would result in saving at least nine-tenths of the sufferers of this disease from the untimely death

to which almost everyone is doomed under ordinary medical treatment." [J.S.]

3.—Trowbridge reports a case of **pernicious anemia** which commenced with malaise, slight rise in temperature, and extreme pallor, there was also some constipation. Blood examination proved the case to be one of pernicious anemia. Death occurred about 5 months after the first symptoms. Trowbridge believes that in those cases of apparent chlorosis in which there is a greenish tint to the skin, the blood should be carefully examined. [J.S.]

4.—Hupp reports a series of interesting **observations on affections of the gallbladder**. Case 1. Cholecystectomy, removal of one large stone by crushing; suture of the common duct; drainage; recovery. The patient presented symptoms of biliary colic without jaundice. At operation, dense adhesions were found overlying an atrophied gallbladder, which bled freely when cut, and about an ounce of thick, viscid bile escaped with some granular detritus. The lumen of the duct was obliterated, though Hupp succeeded in passing a Fenger's probe, locating a mass near the foramen of Winslow. The duct was incised and the mass, which weighed 83 grains, was removed. The duct then was closed with 5 silk stitches; a small rubber tube^t drained from the site of the incised duct, and a large one from the gallbladder, both exposed ends being immersed in a 4 ounce bottle containing a 25% solution of carbolic acid. The small tube was removed at the end of 24 hours, the large one at the end of 10 days. Case 2. Cholecystectomy, 10 large stones; cholecystectomy, 1 large stone; recovery. This patient suffered from jaundice, otherwise the case was the same as the former. Case 3. Cholecystectomy, cholecystectomy, removal of a friable stone, morphin habitué, cholemia; secondary hemorrhage; death. Patient had a former operation for floating kidney; symptoms were about the same as in Case 2. When the gallbladder was opened a large quantity of milky fluid escaped, far in excess of its capacity; adhesions to the liver caused considerable bleeding. Some days after the operation the patient began to suffer from fainting spells. She died on the sixth day. At the necropsy the abdomen was found filled with clots, but no bleeding vessel could be found. Case 4. Gallstones; cholemia, ulceration and perforation of common duct; no operation; septic peritonitis; death. Case 5. Gallstones, ulceration and perforation of common duct; shock and septic peritonitis; no operation; death. Confirmed by autopsy. Case 6. Ulceration, perforation of one of the bile-ducts; symptoms of peritonitis; no operation; recovery. Symptoms were about the same as in Case 1. [W.S.N.]

5. Three Cases of Gunshot Wounds. A. FARENHOLT.

1.—In the routine work of the laboratory, which deals with so much and such varied material, and which constitutes probably $\frac{1}{2}$ of the work exacted of laboratories devoted to public health, there is opportunity given for fine inductive reasoning, which, when put to the test of experiment, may yield very valuable results. Unfortunately, however, either the time for the careful study of the accumulating statistics and facts is wanting, or else the physicians served by the laboratory neglect to furnish the desired data and render the bulk of the material on hand almost worthless. Another difficulty arises from the close relation between the laboratory worker in sanitary science and the public. Leaving aside as well known the frequently discouraging encroachments of politics upon the functions and functionalities of the laboratory, there is danger that the genuine scientist may be misunderstood, undervalued, and eventually driven out entirely. The peculiar situation of the public health laboratory should make the investigator very cautious concerning the conclusions he may publish and maintain. Among the problems that are today clamoring for attention are those that group themselves about the conception of immunity, the

toxins, antitoxins and bactericidal forces, the variations of pathogenic bacteria, and the interrelation of human and animal infections. Crystallized methods are both a safeguard and a danger. They guide us and make our results homogeneous. They may also petrify our modes of thought if we too slavishly adhere to them. In the choice of methods we should clearly define to ourselves our purpose. If we are seeking the solution of new problems, we must create new ways and means. If we are making collective investigations to secure and broaden the basis of accepted facts, our technic must be both uniform and detailed. [J.M.S.]

2.—Moorehouse contributes an article in which he advocates a more liberal diet in typhoid fever. He summarizes 150 cases, some of which are counted twice, that have been treated in 17 months. In 5 cases feeding was begun when the temperature reached normal and was followed by slight irregularities in the temperature. In 39 cases feeding was begun when the temperature reached normal and there was no subsequent rise. In 21 cases the feeding was begun before the temperature reached normal and was followed by a "relapse like" rise of temperature. In 13 cases feeding was begun before the temperature reached normal and was followed by irregular fever, thought to be relapse. In 84 cases defervescence was apparently unaffected by food. In 11 cases defervescence was apparently hastened by feeding. [J.M.S.]

6. A Contribution to the Mechanism of Articulate Speech. S. W. CARRUTHERS.

1.—Foulis reports in detail the symptoms of poisoning experienced by 2 brothers, each of whom had taken 90 minims of tincture of *cannabis indica*. [J.M.S.]

2.—At St. George's Hospital, it has long been the rule for all cases of diphtheria admitted under Ewart's care, to receive local treatment of the nose and nasopharynx, by the introduction of carbolized oil twice daily throughout their stay in the hospital, with a view not only to relieve local discomfort or lesions, and to obviate the spread of the latter, but also to insure, if possible, in all cases, a gradual cleansing and disinfection of the entire mucous surface, by the spreading upwards of the oil, which is dropped in with a camel's hair brush, the patient's head having been thrown backwards. The long local permanence of the seeds of infection in some subjects suggests a question, whether some of the usually late sequels, particularly of diphtheria and of influenza, might not themselves be late infections and the relapses of influenza, autoinfections, perhaps preventable, if the infecting organisms were thoroughly removed. The systematic disinfection should rationally include some endeavor to clear the recesses of the tonsils of their stale contents. [J.M.S.]

4.—Orr reports the case of a female child, aged 7 weeks, who presented a swelling of the belly. On examination of the abdomen, the superficial veins were found distended, and the epigastric and both hypochondriac regions were greatly enlarged and prominent. The surface of this enlargement was perfectly smooth and uniform, presented no irregularity, and no pulsation was visible. Careful palpation revealed the presence of a solid mass which was movable during respiration and which was evidently an enlarged liver. A second enlargement occupied the left half of the abdomen. It was also movable during respiration. The 2 swellings appeared to be quite distinct from each other. The blood was frequently examined, and at first showed decided leukocytosis, which, however, disappeared. The patient steadily lost strength and emaciation began and then slight edema of the lower limbs appeared. The abdomen became increased in girth, and gradually the 2 areas of enlargement and dullness descended into the right and left iliac fossa respectively. A provisional diagnosis of splenic anemia with coincident hepatic enlargement was made. The postmortem examination revealed the fact that the enlargement of the liver was due to the presence of numerous sarcomatous nodules. The primary growth was discovered in the right suprarenal capsule. [J.M.S.]

1. Queirolo's Method of Determining the Outlines of the Stomach. PAUL EDEL and FRANZ VOLHARD.
2. Hematologic Investigations. ERNST BECKER.
3. A Case of Endothelioma Myxomatodes Palati Mollis. H. CORDES.
4. Is the Illumination by the Röntgen-Rays Sufficient for the Differential Diagnosis Between Aortic Aneurysm and Intrathoracic Tumor? E. GEBAUER.
5. Practical Examination of the Chest by Means of the Röntgen-Rays and Some Results. LEVY DORN.

1.—Queirolo's method consists in the use of a stomach-tube, on the end of which there is fastened a small bag. On the free end there are 2 openings, 1 of which is connected with a drum head and the other opens and closes with a stop-cock. The tube is introduced into the stomach, air is blown in through the free end, and by this means the bag is filled and the drum is made tense. The observer then percusses lightly over the stomach region, and observes the influence upon the tambour connected with the instrument. When the actual region over the stomach is reached the recording pencil is set in marked motion. Small movements of the pencil are seen in percussing any portion of the abdomen. Only marked movements must be considered of importance. The method is a useful one, more particularly when used in connection with other methods. The observers note, however, that in some cases results are not obtained because the

stomach contains practically no air. They have discovered that the stomach must be under moderate tension with air in order to give satisfactory results. [D.L.E.]

2.—In the first place, in discussing pneumonia the author notes that 3 very severe cases had a leukocytosis varying from 10,000 to 28,000. All these ended fatally. Two very severe cases which ended in recovery had a leukocytosis of 31,000 and 29,000. A third fairly severe case had a leukocytosis of 17,000, and in a mild case there was a leukocytosis of only 13,000. Hence the mere degree of leukocytosis does not indicate directly the severity of the disease, but a high grade of leukocytosis indicates a severe infection, a moderate leukocytosis, of from 12,000 to 16,000, is seen in both severe and mild cases, while slight leukocytosis is a bad prognostic sign. But if the leukocytosis is of high degree, although it shows a severe infection it at the same time indicates a good reaction; a moderate leukocytosis may indicate slight infection with sufficient reaction or tense infection with a poor reaction; slight leukocytosis may indicate exceedingly slight infection, but as a rule it indicates very bad reaction. The relative number of different forms of leukocytes was not influenced. Eosinophiles were never found in fatal cases, hence their absence is a bad sign. Sometimes the polymorphonuclear neutrophiles showed increased size of nucleus and poor staining. They looked like an intermediate stage between the myelocytes and the polymorphonuclears. In one case myelocytes were found, and their number reached 9%. [D.L.E.]

3.—Cordes records a most interesting case of endothelioma located in the left side of the soft palate. The growth was first noticed 3 weeks previous to the examination. It was removed by splitting the overlying mucous membrane and excising the larger part, a small portion remained and required curetting. The microscopic examination showed that the growth was undoubtedly a true endothelioma which had its origin in the endothelium of the lymph spaces and vessels. The character of the tumor was evident that the endothelium of the bloodvessels had also participated in its formation. The marked myxomatous and hyalin degeneration which was present made the diagnosis more difficult in that it required more time to find the characteristic portions of the tumor. [G.B.W.]

4.—The importance of the present communication is that the diagnosis of a case being in doubt between mediastinal tumor and aortic aneurysm, examination with x-rays was undertaken. A pulsating tumor was seen, and the pulsation was thought to be distinctly expansile. The diagnosis was then thought to be aortic aneurysm. There was dullness under the sternum, Oliver's symptom was present, there was a systolic murmur, and the left vocal cord was paralyzed. However, there was such marked difficulty in swallowing that it was considered unusual for aneurysm. The post-mortem showed a round ulcerating carcinoma of the esophagus, with a communicating abscess cavity, the mass being situated 9 cm. below the interarytenoid folds. The diverticulum formed in the esophagus had become adherent to the posterior wall of the aorta. This evidently explained the tracheal tug, and also explained the apparently expansile pulsation. [D.L.E.]

5.—Levy-Dorn describes the apparatus which he has had made for marking out the areas of shadows seen upon radioscopic examination. It consists of a small rubber balloon connected with a fine sound with an angular end, which is connected with a stylographic pencil. The rubber balloon contains a weak solution of methylene-blue, and this stain is expressed through the pencil as one wishes to mark areas on the chest. [D.L.E.]

Wiener klinische Wochenschrift.

August 23, 1900. [13. Jahrg., No. 34.]

1. A Case of Malignant Endocarditis with Countless Metastases. S. GAVALA.
2. Concerning the Treatment of Epilepsy. MAX BIRO.

1.—Gavala reports a case of ulcerative endocarditis in a man of 20, who had had articular rheumatism 8 months before. When lifting a heavy barrel in an ice cellar he was seized with palpitation and pain in the chest and abdomen, and in a few hours had a chill. The symptoms were those of ulcerative endocarditis. The patient died, and at the autopsy

suppurative tonsillitis and acute pharyngitis were found, in addition to acute endocarditis of the mitral valve, myocarditis, and pericarditis. The case was remarkable for the extensive metastasis that had taken place, affecting the brain, lung, spleen, liver, kidneys, small intestine, and the skin. There was an old endocarditis of the mitral and aortic valves and hypertrophy of the heart. The author looks upon the tonsils as the portal of entry for the germs, which were found to be *Staphylococcus aureus*. In the tonsils, in addition to *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Staphylococcus albus* were found. Regarding the acute onset, the author is of the opinion that there was an acute endocarditis without symptoms before the strain of lifting the barrel, and that the exertion detached some of the endocardial vegetations, scattering infection throughout the body. [D.R.]

2.—It is difficult to say when epilepsy is cured. No definite period can be given; hence the value of methods of treatment is not easily estimated. An approximate standard is found in a comparison between the intervals before treatment and those afterwards. By a careful study of the cases under his observation during a period of years, Biro was able to determine that the epileptic attacks occurred with a certain regularity, and in 2 principal types. The first comprised those in which the attacks increased in frequency, the intervals becoming shorter—a type which he called the **acrescence type**. It was present in 60%. In 20% the intervals remained the same. In 12% the intervals became steadily longer—termed the **decrease type**. The longest interval between attacks is not a criterion of the treatment if similar intervals occurred before. The treatment of epilepsy consists in general measures. The life should be quiet; hence traveling and considerable exercise, whether active or passive, are contraindicated. So are cold douches. Mild hydrotherapeutic measures are valuable. Regarding electricity the author does not express himself clearly. Alcohol and tobacco are harmful. An exclusive meat diet increases the frequency of the attacks. With a milk diet some cases improve; others become worse. A cure was never observed. The occupation of epileptics demands careful attention. Able-bodied persons may work in the field and garden; for the average epileptic, however, some indoor occupation, such as drafting, modeling, or office-work, is indicated. Of drugs, the bromids enjoy the greatest favor. In 33 cases the bromid treatment was carried out systematically for a number of years. Ten cases remained free from attacks for 3 years, and 2 for 5 years. In 30% the drugs proved valueless. The depressing effects of the bromids need not cause concern. They may disappear with continued use. Next to the bromids comes the Fiechsig treatment. This consists in giving opium in ascending doses for a period of 6 weeks, beginning with 0.5 g. ($\frac{3}{4}$ gr.), 3 times daily, until 1 g. (15 grs.) per day is reached. The dose can be increased every 2 or 3 days or once a week. For children of 6 years the beginning dose is .01 g. and the maximum .12 to .19; at 12 years the beginning dose is .3 to .4 g. per day; and from 13 to 16 years .6 to .75 g. The principal feature of the treatment is the sudden cessation of the opium and its replacement by the large doses of bromids, beginning with 6 g. per day (120 gr.). In some of the cases when the bromids had failed to prove satisfactory the **Bechterew treatment** was employed. This consists in the administration of from 4 to 8 tablespoonfuls per day of a mixture of an infusion of adonis vernalis (from 2 to $3\frac{1}{2}$ g. to 18 ounces of water), sodium bromid, 8 to 12 g., and codein .1 to .2 g. **Atropin** has been recommended, and in 1 case the author saw decided improvement from its use. In another case the combination of bromid and antipyrin proved valuable. [D.R.]

2. Special Dangers of Acute Purulent Inflammation of the Middle-Ear in the Aged. HEINE.
3. The Treatment of Empyema of Highmore's Cavity. MAX HALLE.
4. Kidney Operation Where There is But One Kidney, or When Both are Diseased. MANKIEWICZ.

1.—Seifert points out the influence of diseases of the nose on neighboring and distant organs of the body, particularly the influence of mouth-breathing. The latter is observed not only in cases of partial closure of the nose, but also at times when the nose is of normal width but has a very dry mucous membrane, or is even of abnormal width and fails to secrete sufficient mucus. In these cases, which occur especially in young persons, there is a sensation of inadequate permeability of the nose, and this leads to mouth breathing. The swallowing of the decomposing phlegm in some cases may bring about the disturbance of the appetite and digestion, and these may play a part in the anemia often seen in ozena. On the other hand, morbid conditions of the digestive organs bring about disturbances of the upper air-passages. Hyperemia and overfilling of the erectile tissues may be produced mechanically by disturbance in the circulation of the abdomen through tumors, torsion and injuries of the intestines, coprostasis, and especially tympanitis. Particles of food that are vomited may enter the cavities of the nose and produce inflammation, and at times rhinoliths. Pathologic conditions of the nasal cavities may also be connected with **neuroses of the heart**, manifesting themselves as oppression, angina pectoris, cardiacgia, irregularity, acceleration, or slowing of the pulse. Valvular heart disease may bring about nasal changes, chiefly a tendency to coryza, and also hemorrhages. The occurrence of epistaxis without local cause in individuals past 40, is suggestive of **arteriosclerosis**, particularly of the carotid or cerebral vessels. In the absence of cardiac and renal signs and of changes in the peripheral arteries, the ophthalmoscope may sometimes corroborate the diagnosis. In **anemias**, hallucinations, and hyperesthesia of the sense of smell are sometimes noticed. In **leukemia**, the hemorrhagic diathesis may manifest itself in abundant nosebleed. In the other hemorrhagic diatheses the same conditions occur in the nose as in the skin. In **scrofula** the nosebleed may be excessive. Profuse epistaxis also occurs at times in chronic interstitial **nephritis**. Vicarious menstruation in the form of epistaxis may last from 1 to 3 days. Hemorrhoidal patients occasionally have epistaxis when the hemorrhoidal flux does not occur. Girls and women at times complain of coryza with obstruction of the nose a few days before the catamenial period, or of obstinate sneezing. Sometimes the onset of the menses declares itself in an intensification of an acne rosacea. A similar condition occurs in the early months of pregnancy. Some pregnant women have peculiar smell hallucinations and hyperesthesia of the olfactory sense. Scrofula has certain relations to diseases of the nose. Certain acute infectious diseases regularly begin with coryza. The absence of this may be of value in the differential diagnosis between **rötheln** and **measles**. Sometimes there is a diphtheric inflammation in the course of measles, the cause of which is principally the *Diplococcus lanceolatus*, with the streptococcus and the staphylococcus. Chickenpox vesicles are very rare in the nose. In **Scarlet fever** there may be epistaxis in the prodromal stage; in the eruptive stage an exanthem may form on the nasal mucosa. In severe cases the nose may become involved as the result of the extension of a necrotizing pharyngeal affection. Scarlet fever also plays a part in the etiology of empyema of the sinuses. Coryza is rare in **typhoid**, but common in **typhus fever**. In the former epistaxis is common, and may occur at any period of the disease. In **diphtheria** the nasal chambers are often primarily or secondarily involved; in infants particularly, the nose seems to be the preferential seat. **Influenza** most frequently of all the infectious diseases involves the nose. **Parosmia** and **anosmia** are common in that disease as a sequence of olfactory neuritis. The relations between **erysipelas** and the nose are very intimate. In the early stages of **whooping-cough** the upper air-passages, as well as the nose, are affected. There is sneezing, mucoid secretion, and hemorrhage. The latter is common in the spasmodic stage. The author suggests treatment of the nose in the early stage of pertussis with quinin, bismuth, or sodium-scozodolium. Some observers report the occurrence of vasomotor neuritis or nasal hemorrhage in **malaria**. Wounds about the nose may lead to the development of **tetanus**. Among chronic infectious diseases, **tuberculosis** and **lupus** are very common in the nose. Tuberculosis appears in 3 forms: as a tuberculoma, as an extensive

infiltration with ulceration, and as bone disease with secondary involvement of the mucous membrane. The lupus affections of the nose usually begin in the mucous membrane. The primary lupus of the mucosa is often overlooked, and is considered to be simple eczema, scrofulous catarrh, or harmless polyps. In **leprosy** the nose is characteristically altered. It is more often affected than lower portions of the air-passages, and may be the only part attacked. The nasal secretion of lepers is, perhaps, the most important medium in the spread of the disease. **Glanders** may attack the human nose, but not so commonly as it does in horses. Among diseases of the skin bearing a relation to the nose, are eczema, acne rosacea, and pemphigus, as well as lupus. An acne rosacea may be intensified by a hyperplastic rhinitis, and the removal of the nasal disease improves the former. Regarding **syphilis** of the nose, it has been shown in the last decade that primary lesions of the nose are becoming more frequent. Much rarer than nasal syphilis is gonorrheal inflammation of the nose. It occurs in the newborn in connection with gonorrheal ophthalmia, and also in adults. [D.R.]

2.—While acute **otitis media** under proper treatment is, as a rule, not a serious disease, it may at times in patients beyond the fortieth year become a very dangerous malady. Heine found among 63 cases of uncomplicated meningitis, 31 in which the fatal disease was due to an acute or a sub-acute, and 32 in which it was due to a chronic otitis media; but while among the latter there were only 5 beyond the fortieth year, in the former 16, or more than half, were over 40 years of age. Four illustrative cases are cited. They show that the danger of the disease is due to its insidious character and the absence or insignificance of the symptoms that usually point to an implication of the mastoid process and lead to a timely operation. The peculiar condition of the bone and certain anatomic relations in advanced age are a factor in obscuring the condition. As a rule the spread of the disease is indicated by tenderness on pressure of the mastoid process. If the disease extends and destroys the osseous partition walls, it will spread towards the surface and bring about a periostitis with swelling and infiltration of the skin. Eventually the pus may burst through the outer layer or a subperiosteal abscess may form. In 4 of the 16 cases a fistula formed in the bone; in one there was an infiltration of the soft parts, and only in 7 was there tenderness of the mastoid. In 4 there was no pain on pressure at any time during the disease. If there is persistent, profuse, purulent secretion, the conclusion is warranted, even without other symptoms, that there is destruction of the bone. In many cases the conditions for the formation of a large pus-cavity are not given, on account of sclerosis or eburnation of the bone. If the inflammation has once attacked the petrous portion of the temporal bone, opening of the mastoid is not apt to bring permanent relief. In 3 cases an extradural abscess formed in the posterior part of the skull; disease of the tegmen tympani was the cause of the meningitis in one; in one the suppuration extended along the carotid canal, and 3 times along the labyrinth. The time that elapses between the acute inflammation of the ear and the development of meningeal symptoms varies from 4 to 20 weeks. It is longest in those cases in which inflammation extends by way of the labyrinth. It would not be wise to open the mastoid in every case of suppuration lasting a long time. Operation is not even necessary in every case in which there is swelling of the soft parts over the mastoid, but the **temporizing treatment is only permissible in young individuals**. In advanced life the operation is indicated in every case in which there is tenderness on pressure over the mastoid process. A symptom of importance is intense headache, especially on the affected side. If it sets in after the beginning of the ear disease and persists even after the outflow from the tympanum is abundant, it constitutes an indication for operation. [D.R.]

3.—Halle advocates the treatment of **empyema** of the **antrum** of **Higmore** by opening through the lower nasal fossa, as was first suggested by Krause. The method of operation is as follows: The mucous membrane of the lower nasal fossa is anesthetized by local application of 10 to 15% cocaine solution; Krause's trocar is then introduced close to the septum; it is passed along the cartilaginous septum and the point is directed laterally and a trifle downward at an acute angle, so that the opening will be made near the bottom of

the antrum. The instrument is introduced by gradual firm pressure with a boring motion, and after the bone is penetrated, it is pushed further until the hilt of the trocar enters the nose. The advantages of the method are that the operation is not difficult and is easily carried out without general anesthesia in a short time. It avoids abnormal communication with the mouth and the disagreeable taste of pus and iodoform. Healing results in most cases in a very short time, and, what is most important, it is as permanent as results from the use of other methods. Halle believes that this method should be tried first in every case of empyema of the antrum. If recovery does not follow, as occurs in rare cases, or if the patient can remain but a short time under treatment, the opening through the canine fossa is indicated. Opening through the alveolar process is recommended only in cases where a hole already exists after the extraction of a carious tooth. The opening of the antrum through the alveolar process by the extraction of a sound tooth he considers entirely unjustifiable. If recovery does not follow after opening the canine fossa and removing the granulations, he recommends operative attempt to close the fistula into the mouth and to bring about healing by an opening into the nasal cavity. [M.B.T.]

4.—Mankiewicz recommends the greatest conservatism in the **surgery of the kidney**. Surgical intervention is only permissible after the operator has used every means to determine the presence of functional activity of another kidney. In doubtful cases it is unjustifiable to remove the kidney, and nephrotomy should be performed. Later on, after sufficient observation, nephrectomy may follow. The most certain method of determining the condition of the kidneys is the investigation of separate urines after catheterization of the ureters, and particularly after subcutaneous injection of phloridzin to produce glycosuria. [M.B.T.]

2.—Bier says that the injection of **cocain into the lumbar spine** is most apt to be followed by severe symptoms which may go on to collapse, and even in one case reported death followed. The more common of the evils which follow cocainization of the spine are vomiting, headache, dizziness, and general weakness, which last for about 24 hours, but which may go on for 8 days before ceasing. And these symptoms may follow the minutest doses. For these reasons he believes that the time for cocainization of the spine to be introduced into general practice is not yet ripe, and especially would he warn surgeons from the injection of large doses, 15 mg. being the largest that should be used under any circumstances. [G.B.W.]

3.—Plato found that albuminous particles enclosed in living leukocytes (phagocytes) stained with neutral red. The staining of the enclosures depends upon the condition of the enclosing cell. If, by an injection of bouillon into the peritoneal cavity of a guinea-pig, an exudate is produced, and then recent gonorrheal pus is injected into the abdominal cavity, the human leukocytes are soon taken up by those of the guinea-pig. The nucleus of the included leukocyte stains with neutral red, but the gonococci contained in it

remain unstained. On the other hand, the nucleus of the enclosing guinea-pig leukocyte remains unstained, while the gonococci in this leukocyte are intensely colored and soon swell. The decolorization of the enclosed bacteria is brought about by the reducing action of the cells. It has been shown that **damaged and dying protoplasm** is endowed with strong **reducing powers**. The appearance of this decolorization is a criterion of the vital state of the cell. As the phagocytes die they gradually reduce the coloring matter in the enclosures and thus decolorize them. Living bacilli, as for example anthrax bacilli, contained in cells, may sometimes stain with neutral red; but very soon they are decolorized and, at the same time, they become swollen. In that case the cell is vanquished by the bacillus which it has taken up. This victory manifests itself in a decolorization of the bacillus and a swelling of the cell. Later, the intracellular bacilli multiply, and finally destroy the cell entirely. When the bacillus has been killed by previous heating and is then taken up by cells, it stains intensely and eventually becomes broken up into a deeply staining granular detritus. Natural immunity can also be studied by means of neutral red. If living gonococci are brought into contact with guinea-pig leukocytes, the gonococci swell, and lose their characteristic form. This does not occur in gonococci incorporated by human leukocytes. Damaged cells with numerous unstained gonococci are often found. The fewer the gonococci, the more they seem to suffer from the phagocytic cells. The different bacteria stain differently with neutral red; gonococci, stains a fuchsin red; staphylococci and certain diplococci, an orange or yellowish-red; anthrax bacilli, an orange or brownish-red, but the color depends to a large extent upon the vital condition of the cell and the state of swelling of the bacteria. [D.R.]

4.—In the lower vertebrates there are 3 organs that are considered adrenal glands, the elongated body situated in the median line in front of the aorta, and known as the **interrenal organ**, which is originally paired, but fuses later into one structure, and the other 2 glands which are symmetrically disposed, run parallel with the interrenal organ, lie above the protonephros, and are called **suprarenal organs**. Their origin, it is generally assumed, is from the sympathetic. In the higher vertebrates and human beings, the adrenals consist of the medulla and cortex. It is held that the former is homologous with the suprarenal organs of the lower vertebrates, while the cortex is supposed to represent the internal organ. The accessory suprarenal glands are looked upon as dislocated parts of the principal organ, and have been considered to be analogous with accessory spleens, thyroids, etc. The author's studies lead him, however, to quite different conclusions. He believes that the **adrenals of man and animals have no relation to the sympathetic**. The nerve structures found in them enter after the formation of the organs. The first *anlage* of the adrenals develops from a section of the protonephros. He also shows that the so called accessory adrenals found in man near the testis and in woman in the broad ligament, are normal structures derived also from a section of the protonephros. The adrenals of man correspond to the interrenal body of the lower vertebrates, while the adrenals found near the testicle and in the broad ligament are homologous with the suprarenal bodies. He thinks that they should really be called by that name or **Marchand's adrenals**, since Marchand was the first to describe them. The adrenals in man are not nervous organs. That they are is a view that is based upon the erroneous conception of the origin of the medulla from the sympathetics. The various theories regarding the functions of the suprarenals are briefly mentioned. Aichel dismisses the view that the organs have any importance in the development of the fetus. The same is done with the theory that they are concerned in the blood formation. That they have something to do with pigmentation has not yet been proved. There appears to be a relation between the **sexual apparatus** and these glands. The effects of extirpation have been equivocal, probably because no attention was paid to Marchand's adrenals, which might intercede after the extirpation of the major organs. Removal of both glands at one time is fatal; removal of the organs separately after an interval is usually well borne, probably because Marchand's adrenals have time to compensate functionally. [D.R.]

5.—Mond, from his own experience and from a review of literature on the subject of **pregnancy and ovarian tumors**, considers the following points as authorized: 1. Ovariectomy is the justifiable therapy as soon as an operable ovarian tumor has been diagnosed during pregnancy. With the increasing size of the tumor there will be conditions favorable for firmer adhesions, thus complicating the removal; for this reason there should be laparotomy as soon as the diagnosis is certain. 2. According to present statistics, to obtain the best results for the mother, the operation should be between the second and fourth months of pregnancy; for the continuance of pregnancy, between the third and fourth. 3. The dangerous complications resulting from delay, such as torsion of pedicle, suppuration of cyst, etc., demand immediate operation. 4. Puncture of cyst and artificial abortion are only makeshifts and not therapeutic measures. In dubious cases puncture is allowable, and eventually, incision. 5. A growth of the tumor in pregnancy is observed in most cases. 6. If the pregnancy is far advanced when the patient is first seen, then also ovariectomy is indicated. 7. During labor even a reposition of the tumor under narcosis may be attempted. In case of small cystic tumors, puncture, or even incision, is indicated. 8. In case of a solid tumor and living fetus at the time of labor, cesarean section is indicated with a removal of the obstruction to delivery. 9. After delivery we should wait 1 or 2 weeks before operating, until the question of puerperal infection is decided and involution of the uterus far advanced. 10. During the puerperium, an enlargement and growth of the tumor has been observed. [W.K.]

6.—A pale girl of 18, who was said to have passed through several attacks of chlorosis, began to have headache and dimness of vision, the latter rapidly passing into complete blindness. The ophthalmoscope revealed optic neuritis and a patchy retina, such as is seen in retinitis albuminurica. The urine was free from albumin and sugar. A diagnosis of **cerebral tumor** was made. In the further progress of the case the patient lost the sense of smell, developed epileptoid convulsions with paralysis of the right arm, and anesthesia of the entire right half of the body. The optic neuritis passed into atrophy, the patient became somnolent, emaciated rapidly and soon died. Earlier in the disease the blood-count had shown 3,000,000 red corpuscles, no leukocytosis, and 50% hemoglobin. At autopsy a tumor was not found, and the only conditions in the brain that seemed to be abnormal were anemia and dryness. The author believes that the optic neuritis was dependent upon a chlorotic condition of the blood; the other nervous symptoms he attributes to hysteria. [D.R.]

7.—Maillefert reports a case of **fracture of the second metatarsal bone**, an injury which is very common in the German army, but somewhat rare in civil life. The patient while attempting to spring from the edge of a water barrel slipped and felt a sharp pain shoot through his foot. The pain, however, disappeared in a short time and the patient was enabled to go on with his work. The next morning the foot was markedly swollen, the pain and disability increased until the patient was unable to put the foot on the ground. Crepitus and the x-rays confirmed the diagnosis. By rest in bed the bones rapidly united and the man returned to his work in about 4 weeks. [G.N.W.]

8.—Kraemer reports the case of a child which was born with blunt angled bend in the right leg which terminated in a clubfoot. The mother said that during the fifth month of pregnancy, when attempting to lift a very heavy chest, she was seized with such an intense pain on the left side that she sank to the floor. The fracture of the fetal bone undoubtedly occurred at that time. While the majority of **intrauterine fractures** result from direct violence, this case belongs to the rare instances in which the break was due to the indirect action of the force. [W.K.]

9.—In this case the patient had endeavored to end her life by opening the abdomen with a pair of scissors. The **intestine was wounded** in at least 12 places, and in one place was entirely divided. The surroundings were such as to render absolute asepsis impossible, but an attempt was made to save the patient's life. The different intestinal wounds were sutured with silk, mostly by interrupted sutures and a rather severe arterial bleeding stopped by a properly placed stitch. A gauze drain was carried out of the median end of the wound and the walls of the abdomen closed by 3 sutures of silk. The patient made a good recovery and was seemingly improved mentally by her experience. [O.B.W.]

Original Articles.

CONVEYANCE OF YELLOW FEVER INFECTION.

By J. O. COBB, M.D.,

of Port Stanton, N. M.

Passed Assistant Surgeon, Marine-Hospital Service.

I CANNOT let the article by Dr. Reed and his assistants on "The Etiology of Yellow Fever," in the *PHILADELPHIA MEDICAL JOURNAL*, of October 27, pass without pointing out some seemingly faulty deductions, and very nearly an error by implication, inasmuch as Dr. Henry R. Carter, of this Service, is quoted in reference to the Orwood and Taylors epidemics in the State of Mississippi.

The references are :

"We were also very much impressed by the valuable observations made at Orwood and Taylors, Miss., during the year 1898, by Surgeon Henry R. Carter, U. S. Marine-Hospital Service. (A note on the interval between infecting and secondary cases of yellow fever, etc., reprint from *New Orleans Medical Journal*, May, 1890.) We observe that the members of the yellow fever commission of the Liverpool School of Tropical Medicine, Drs. Durham and Meyers, to whom we had the pleasure of submitting Carter's observations, have been equally impressed by their importance. (*British Medical Journal*, September 8, 1900, pp. 656-7.)

"The circumstances under which Carter worked were favorable for recording with considerable accuracy the interval between the time of arrival of infecting cases in isolated farm houses. According to Carter, 'the period from the first (infecting) case to the first group of cases infected, at these houses, is generally from 2 to 3 weeks.'

"The houses having now become infected, susceptible individuals thereafter visiting the houses for a few hours, fall sick with the disease in the usual period of incubation, 1 to 7 days.

"Other observations made by us since our arrival confirmed Carter's conclusions, thus pointing, as it seemed to us, to the presence of an intermediate host, such as the mosquito, which having taken the parasite into its stomach, soon after the entrance of the patient into the noninfected house, was able after a certain interval to reconvey the infecting agent to other individuals, thereby converting a non-infected into an 'infected' house. This interval would appear to be from 9 to 16 days (allowing for the period of incubation), which agrees fairly closely with the time required for the passage of the malarial parasite from the stomach of the mosquito to its salivary glands."

Dr. Carter established the Service quarantine for Taylors and Orwood, and I had charge of it immediately afterward. Much of the information of the cases referred to in Dr. Carter's article was collected by Drs. Harralson, Gant, and Birchett, of the State Board, and Dr. von Emdorf and myself, of the Service. The notes of Dr. Birchett were the most painstaking I have ever seen, and it was on these notes that Dr. Carter placed the most reliance, as Dr. Birchett's service was principally in taking care of the sick. Dr. Carter had believed previously that it took about 14 days to establish a secondary infection, and instructed us all to keep this well in mind and make careful notes on all sides of the question. He furthermore believed that the fever was not contagious, but that it was altogether infectious. Believing this as he did, it was necessary for a period of incubation to take place in an infected house. All our previous epidemics, with the exception of McHenry, had been mixed up in such a way that it was impossible for us to keep track of the exposure. Here at Taylors and Orwood we had the most advantageous epidemic for study that has yet existed, as the country

was sparsely settled, practically free of malaria, and the disease occurred among a class of people who could and did help us in our close investigations.

Taylors, Miss., is a small railroad station on the Illinois Central Railroad, about 20 miles south of Oxford, and a few miles north of Water Valley, these two towns being the only ones nearby with a population of over 1,000. Taylors, Orwood, and Oxford lie in what is known as the "Black Jack" belt. This region is on rolling red hills, covered by scrubby oaks, these trees being popularly known as "Black Jacks." There are many such sections throughout the South, and any one familiar with these sections knows that they are high, dry and nearly always free of mosquitos.

Having been a partial, though weak-kneed, convert to Finlay's mosquito theory, before I had had any experience with the disease, I was naturally alert to the conditions existing at Taylors and Orwood, when I first went there.

At Taylors I slept in an old hall room, over a country store, which was about 200 feet from a ravine, which ran through the town. This ravine was about 20 feet deep, being what is popularly known in the South as a large gulley. It carried off flood water from rains, and at places there was some seepage into it at times, being enough to make it damp in the lower part of the town. There were no privies emptying into this, except the one near the railroad track and which is mentioned in my report to the Surgeon-General of 1898. In my room I noticed there were mosquitos and I had to have a mosquito net. I have also seen mosquitos in the ravine.

I am not familiar with the names of the different species of mosquitos, but this insect was the large gray variety that I have always heard called the woods mosquito. A mile north of Taylors was Mr. Seisenger's house, where there was a virulent case. I made a necropsy on this case in the presence of Drs. Carter, Harralson, and Gant. All agreed that the patient had succumbed to an immediate attack of yellow fever, but that it was mixed infection, the pathologic manifestations of malaria being unmistakably present. This house was near a small swamp, and there were many mosquitos in and about the house. Mr. Seisenger lived there for many years and he could hardly have contracted malaria elsewhere. During the entire service at Taylors and Orwood I did not see another case of malaria, though at Oxford I saw quite a number of undoubted cases on the east side of the town, which is near a large pond. Aside from these places, with possibly some that I did not investigate personally, there were no mosquitos in Orwood or Taylors.

It is well known that the mosquito does not travel very far from its immediate surroundings; however, I am prepared to admit that some species of mosquito are carried great distances in storms, and many voluntarily fly for considerable distances. I am also convinced that this particular variety of mosquito breeds in the woods and not necessarily in large pools of water.

It is unfortunate that my investigations were not closer in regard to the mosquito. I became so welded to Dr. Carter's secondary infection theory that I may have grown careless about other theories, and what I have to say on the subject must be viewed from the standpoint of possible error, as my observations were merely incidental.

So far as Orwood is concerned it is only a mere set-

tlement, and the houses are far apart; in fact, nearly invariably a mile or so apart. We all know that the southern farmer, as a rule, tries to build his house on high ground, and nearly always near a good, rapid-flowing spring.

We might take one case as an example for discussion. At the post-office seat of Orwood there lived a family by the name of Gray. The house was made of logs, and very open to all kinds of weather. It was the old style log-house of the South. The people were poor, but far above the average in intelligence, and their stories were accepted with more credence than given to most others. There is no running water near this house, and the water-supply was procured from a well which was very deep, and which barely supplied enough for domestic purposes. I slept in a tent in this yard several nights, and I am positive there were no mosquitos, for if there had been they would have surely hunted me out, as I am very susceptible to their attentions; furthermore, the bite of the mosquito poisons me severely, and if bitten in the night I would have surely known it. This family consisted of five members, and the disease ran through the entire family in strict accordance with Dr. Carter's prediction and idea of secondary infection. The young lady of this house was exposed seriously in another house 5 miles away. She went home sick and about 14 days later her mother followed, and then so on through the entire family until all had the yellow fever. I could enumerate many similar cases in which it is hard to believe that infection was conveyed by insects, especially by the mosquito. I would more readily believe that the bedbug or other animal parasites become the hosts of the germ than the mosquito.

One other case seems hard to understand from any standpoint and I would like to introduce it merely as showing the great difficulty that the practical quarantine officer experiences in trying to prevent the spread of yellow fever. The following is a letter written to Dr. Carter, but which was probably lost in the mail, as it never reached him, viz:

TAYLORS, Miss., September 27, 1898.

Surgeon Henry R. Carter, U. S. Marine-Hospital Service,
New Orleans.

DEAR DOCTOR CARTER: Knowing your desire for thoroughness in all quarantine matters, and believing as you do in the possible conveyance of fomites of yellow fever by one's person, I have to submit at this time for your consideration a case well illustrative of the point, or at least well worthy of close study. If we can establish this case as introduced by fomites, it seems to me that it would be well to promulgate a rule of action for all officers operating in your field in regard to personal disinfection; for while you have already set us the example by your own actions under all circumstances, with often great inconvenience to yourself; however, your initiative may not receive the consideration from others which the importance of the subject really demands. The case in point is as follows:

David Jones, aged about 45 years, was taken sick September 16 at 9 A.M. The patient developed into a well marked yellow fever case, dying at the end of 7 days. Mr. Jones was in the Gray house on August 9 and shaved Dr. Gray after he was dead. His son, a young man about 22, helped Mr. Jones shave Dr. Gray. This young man also "sat up" with Hampton Williams the night before young Williams died, which was on August 10. The razor and shaving materials were left at Dr. Gray's house. Mr. Jones took no precautions at all, for at that time no one knew of the fact that the deaths had been caused by yellow fever.

On August 27 Mr. Jones was in Taylors and talked to a Mr. Ragland about 10 minutes, Mr. Ragland being two days out of bed from sickness which was probably yellow fever,

as since his entire family has developed that disease. On August 30 Dr. Gant declared the prevailing sickness to be yellow fever. From that time to the date of his death, Mr. Jones never left his farm, which is four miles away, except to act as road guard a short distance from his farm, and once going into his father's house, September 11, which was free from infection. He was very anxious about his exposure, but felt comparatively safe, as such a long time had elapsed since exposure. He allowed no one to visit his house, nor did any member of his family leave the farm after August 30. No letter, no package, no food, nothing whatsoever went into his house after that time. The members of the family are intelligent, respectable, honest and well worthy of belief; and, so far as I can find, no exposure to an infected focus has taken place by any of them. Accepting then that the facts in the case are as stated, and that there is no error, let's look at the dates.

Mr. Jones was exposed to the town of Taylors, riding along the ravine by the Sisk houses and later talked to Mr. Ragland about 10 minutes on August 27, or 21 days before taking sick. That period of incubation certainly seems long. Now, there is one phase of the question, which, if we could establish, would make it plain sailing, and that is a previous case in that house, but unfortunately we cannot do that. Yet we have a sick child to consider.

John Jones, age 8 years, in perfect health previously, was taken sick with a rigor, followed by fever at 9 o'clock A.M., on September 16, or at the same time his father became sick. He was put to bed and it was thought that his fever had subsided by noon. He was seen on the second day by Drs. Gant and Birchett, who thought it to be a case of malarial fever, as there was no fever at the time of their visit. The child was given four doses of "chill tonic" on the second day, but the fever coming up that night the medicine was discontinued. The boy's fever continued about 5 days. I saw him on September 24 and 26. His pulsations were 70, he was weak, had clean tongue, was hungry, never had albumin in the urine, gums were spongy over the arches of three teeth above and beneath four below. Looked anemic.

Dr. Gray died August 9 and Hampton Williams August 10. Mr. Jones was taken sick September 16, or 37 days after exposure to Dr. Gray—a long time for the secondary infection it is true. The other exposure is 21 days, but does not seem to deserve consideration from the standpoint of conveyance of infection by fomites.

I can only conceive that the conditions at Mr. Jones' house were such that the secondary infection was of slow development, or sufficiently attenuated to pass upon the supposed incubation period of secondary infection to a time when atmospheric or other conditions made the focus operative or dangerous.

After Mr. Jones' death, the family were removed from the house and put in tents. So far all are well, but the incubation period has not yet passed.

This to me has always been a very puzzling case. I never slept at this house at night, and never asked the family if there were mosquitos, but the facts of the high location, and the great isolation of the house, the strict guard kept, the absence of contact, the keeping out of even letters and newspapers, make it exceedingly puzzling for the mosquito theory or any other theory. It is not probable that the mosquito travels 4 miles, and it was about 4 miles to the nearest infected house. Mr. Jones was undoubtedly the first case in this house.

Dr. Reed does not say so, and yet in his article he conveys the impression, that the disease may be only carried by the mosquito feeding on the blood of persons suffering with yellow fever. Of course one cannot always cover every little point in a discussion of this kind; and it is presumed that Dr. Reed would admit that the stools of yellow-fever patients may contain the specific organism, and if so, it is quite probable that the organism does live outside of the body and that the mosquito might obtain the infection from a cesspool or other infected point and thus convey the

disease. For sake of speculation we will grant that this is true, for if we do not Dr. Reed's mosquito theory would be untenable in the face of the facts of the McHenry outbreak in 1898. The recrudescence at McHenry, for surely it was such, is hard to explain from the mosquito standpoint, unless, as mentioned above, he will admit that the mosquito may secure its infection outside of the human body.

The following quotation is taken from Surgeon J. H. White's article, page 544, Annual Report of the Marine-Hospital Service, 1898, viz :

"It has been vigorously asserted that yellow fever may not hibernate from one summer to another in the United States. This outbreak gives proof to the contrary, following as it did the epidemic of 1897, which, as is now known, began in Ocean Springs as early as April, but was not recognized until the last week of August, and which visited 42 cities and towns in 10 States, with a total of 4,429 known cases and 484 deaths. The Service undertook a post-epidemic disinfection of the infected towns. It has now been ascertained that in May of the present year, although McHenry had been subjected to the post-epidemic disinfection, there was a focus of infection, which, by reason of its peculiar character, had not been suspected and had not been disinfected, namely, an ice-house which had been used as a dumping-place for refuse, including dejecta, during the prevalence of yellow fever in McHenry in 1897; no ice had been stored in it since the summer of 1897, but it was partly full of rotten sawdust. The first 2 cases occurring in McHenry worked together in cleansing this ice-house some 7 days prior to attack. They had nothing else in common, and were taken sick almost simultaneously."

After reading this quotation one cannot help but ask why yellow fever not spread in certain zones. It is claimed that, with hundreds of people fleeing from infected localities to Nashville, Tenn., not one local case ever developed, and that the disease has never spread from cases coming there with the disease; still mosquitos are bad in Nashville; however, they may not belong to the variety of the *Culex fasciatus*. In Atlanta, upper South Carolina, and western North Carolina, no cases have ever developed, notwithstanding the influx of exposed persons. There are no mosquitos in upper South Carolina and western North Carolina, except here and there in swampy and low marshy places. I am not familiar with Atlanta. If we pursue our thought along this line, how shall we explain the spread of the disease aboard ships at sea; especially how shall we explain the frequent outbreaks aboard the *Plymouth*. This vessel was broken and frozen out twice, and thoroughly fumigated a number of times. She went to sea from Boston March 15, 1879, and all will recall that as soon she ran into hot weather a well-marked case developed 6 days after going out and being out of sight of land all this time. The life of the mosquito is short in summer, but they do hibernate and live through the winter, even at zero temperature. I once saw mosquitos on snow with a temperature close to zero. I mention this especially as bearing on the case of the *Plymouth*, for it seems hypothetical in the extreme that the mosquito should have lived through the exposure of -15° during the winter of 1878-79; with the very thorough sulfur disinfection; with a thorough washing out and tearing out of the vessel; and yet revive itself and produce the disease in 6 days after reaching the tropics. Now, if the mosquito was in the hold of this vessel, it must have been infected from the cases of the summer previous. I do not say this is impossible, for it is well known that bacteria will not perish in ice for periods of years, and if the mosquito is truly a hibernating insect, it is

certainly possible that it was stored away in some of the many recesses of the ship where sulfur did not reach; and that the yellow-fever germ had in this case also survived in the body of its host. This is entirely within the limits of possibility, and I furthermore believe it possible for the mosquito infected with the plasmodium to hibernate and produce malaria the following spring.

It seems to me that the hardest blow to the mosquito theory is the fact that it is nearly invariably 14 days after an attack in one house before there is another case developed. It is true Dr. Reed uses this to support his position, but it would seem untenable in face of the fact that the incubation period of yellow fever is usually 5 days, and even in houses nearby cases do not develop unless elsewhere exposed, in houses in which there has been a case of fever at least nine days before. This is a rule, but in Taylors a young lady and her young brother shut themselves indoors and were not exposed for weeks, but finally towards the close of the epidemic both contracted the disease. This house was on the opposite side of the ravine, directly in front of the badly infected Sisk houses, but at least a hundred yards away. This house was under my personal observation daily and was watched with much interest. I have heard Dr. Carter tell of a similar case, the distances being about the same. Here the yellow-fever germ must have traveled and spread out to these points, or it must have been our friend the mosquito, becoming infected on some case at the Sisk houses and then making an excursion, carrying the disease to these people.

As I said before, the mosquito does not travel great distances, but that he takes up his abode at one house and remains there in every instance is hardly probable; and that he would go to one house from another is likely. And yet we do know that after a mosquito has filled with blood, it usually seeks some dark and secluded spot and remains there until the blood is digested. Even though we may accept these facts, it will not explain the practical experience that many Marine-Hospital officers have had, that removing the family from an infected house to tents nearby will cut short the spread of the disease. In all our experience in the service it has never been proved that yellow fever spreads in camps made of tents, notwithstanding that the places where these camps have been established were infested by myriads of mosquitos. At Fontainebleau and Camp Hutton mosquitos are very bad. Cases of fever developed here in five days after exposure outside, but there were never any developed in the camps among those who had passed the incubation period of outside exposure.

The bacteriologist of theoretic turn of mind very often needs to have his experiments controlled by the practical worker, and the expressions of the practical observer nearly always help the seeker after truth, be he ever so gifted. Such work as Dr. Reed and his assistants have performed must receive the serious consideration of every bacteriologist and epidemiologist who may be interested in the subject of yellow fever. But, if a worthy theory is advanced, which however, does not meet the views of any one particular man, or set of men, such an investigator or set of investigators, in all honor, must go over step by step the points brought out and either prove or disprove them and not jump to another line of investigation unless such investigation will control the steps

of the first named. We respect Drs. Sternberg, Reed, and their assistants most highly, but we are not prepared to accept their mere negative positions as disproving the validity of the Sanarelli germ as the cause of yellow fever or as establishing the identity of this germ with Sternberg's *Bacillus X*. These gentlemen have not disproved the work of Wasdin and Geddings and others, and until this is effected by thorough and careful laboratory work, under the same conditions as Wasdin and Geddings worked, most of us cannot be as receptive of the mosquito theory as we otherwise might be. Personally I am prepared to believe that mosquitos, and even bedbugs and fleas, may convey this disease. I never could see any reasonable cause for the suppression of the disease in certain sections of South Carolina or Georgia, which are practically free of mosquitos, unless it were that this insect does convey the infection. In these sections the nights are hot, and the sanitary conditions in many places bad. In 1897 thousands of people fled from New Orleans to points in Illinois and other northern States. Many of these undoubtedly went to places where there were mosquitos, and still there was no spread of the disease. It will be recalled that the summer and early fall of 1897 was hot throughout the North, and I know that Dr. Murray, of our Service, was in fear that the disease might spread in Chicago or some other large northern city. And, to my mind, there is no good reason why it did not, and why it may not, if introduced in a hot summer.

It is discouraging to think that the mosquito may be the sole conveyor of the disease, for we cannot now expect to confine the disease to each infected house as we have heretofore tried to do. Undoubtedly some infected mosquitos will certainly elude us and escape to other nearby houses. Yet this is not the practical experience of Marine-Hospital officers, for we have shut up the disease and prevented its spread under the most discouraging circumstances, and, as I recall, even in the presence of mosquitos. In the midst of speculation let us not lose sight of the practical and keep in mind that the disease can be confined to narrow limits by the *cordon sanitaire*, carefully officered by trained quarantine officials. Such a service was that at Hampton last year.

THE OCCURRENCE OF MALTA FEVER IN MANILA.*

By RICHARD P. STRONG, M.D.,

Assistant Surgeon, U. S. A., Director of the Army Medical Laboratory, Manila,
and President of the Board appointed by the Secretary of War for the
Investigation of Tropical Diseases in the Philippine Islands,

AND

W. E. MUSGRAVE,

Hospital Steward, U. S. A.; Resident Pathologist to the First Reserve Hospital.

IN Manila one naturally meets with a number of fevers quite distinct from those better known in temperate climates. These fevers, which are continually being seen in our large military hospitals, are often a veritable puzzle to the conscientious observer and diagnostician. So far as we know no attempt has been made towards describing or classifying them either from a clinical or pathological standpoint. Indeed, an accurate classification of all seems hardly, with our present knowledge, possible. While in our wards we always

see typhoid and malarial fever, the cases of these two diseases all taken together do not form more than 60% (or 70% at most) of all our cases of fever. In a hospital of this size (1,300 beds) many cases naturally go down on our records with the diagnosis of malarial fever that are not malarial in origin, or in which, at least, no plasmodia have been demonstrated or no blood-examinations made.¹

Allowing for a certain percentage of patients suffering from dengue fever, which percentage varies markedly from time to time, there have still been a considerable number of cases of fever of undetermined origin or diagnosis.

It therefore seems of importance that each type of fever which is recognized here should be at least mentioned, as each variety known naturally throws some light, however small, on the separation and classification of the more imperfectly differentiated fevers which exist here.

The following cases are therefore considered worthy of report:

CASE 1.—For the clinical history of this case we are indebted to Dr. Robinson, acting assistant surgeon, U. S. A. The patient was a man, aged 21 years, and a member of the 51st Iowa regiment, which had been in Manila for about a year at the time he was taken sick. When the case came under Dr. Robinson's care, at this hospital, the patient gave a history of fever of nearly 2 months' standing, and was already anemic and extremely emaciated. His night-sweats were profuse and he complained at times of pain in his ankle-joints and in the left side of his face. The joints were never reddened nor swollen, however; the tongue was coated with a brownish fur; he had at first no delirium, but towards the end slight delirium developed. The bowels were slightly constipated; his pulse became rapid, feeble and running, and the temperature rose to 105.4° F., on the evening of the twenty-eighth day after his admission into this hospital, when he died. The temperature was very irregular throughout (vide chart). It is unfortunate that we have no record of his temperature before his admission to this hospital.

This first case came under our notice at necropsy, where, from the absence of gross anatomic lesions and the clinical history of the case, it was regarded for the moment one of typhoid infection without intestinal lesions.² But at the necropsy the cover-slips from the spleen and liver showed no bacilli, and after 48 hours in the incubator there was still no apparent growth in the cultures from these organs.

NECROPSY.—The necropsy, performed 13 hours after death, shows the body of a considerably emaciated man; rigor mortis is well marked in both upper and lower extremities; moderate livor mortis is present over the back and dependent parts; the right arm and forearm are both swollen and discolored, the tissues edematous and distended; the intercostal muscles are a little redder in color than normal.

Pericardium.—Both layers of the serosa are smooth; the cavity contains about 35 cc. of clear fluid.

Heart.—The vessels of the epicardium are considerably injected, and there are small, diffuse hemorrhages in their regions; the right auricle is free from thrombi. The valves of the heart are all normal, with the exception of a diffuse reddening (probably postmortem) of all of them and of the endocardium in general. Aorta: The arch shows a number of patches of early atheroma; it is also diffusely reddened. The left coronary artery wall shows likewise a reddened internal surface, its lumen is patent; there are several small calcareous plates in the vessel wall. The left coronary, just at its entrance above the free edge of the valve, contains a calcareous mass, partially filling the lumen of the artery. The artery along its course shows other small calcareous plates. The heart is somewhat small and flaccid; on cut section the muscle is a little pale and brown in color; it shows no microscopic evidence of fragmentation.

* From the Army Medical Laboratory, Manila.

Bacteriology.—Cover-slips were made at the necropsy from the heart, liver, gallbladder, spleen and distended tissues of right forearm. They were all negative for organisms. Two agar plate cultures were made from the spleen and one each from the liver, kidneys, heart's blood and swollen tissues of forearm; the plates were all placed in the incubator at 37° C. After 24 hours they were examined and were apparently all sterile. They were placed again in the incubator, but after 48 hours there was still no apparent growth. On the morning of the fourth day of their stay in the incubator, however, the two cultures from the spleen and the culture from the liver showed a number of colonies (more

abundant in those from the spleen), apparently similar, both on the surface and in the depth, too numerous to be considered as air contaminations. The plates from the kidney, heart's blood and arm were negative still for organisms and remained so.

These colonies on the plates made from the liver and spleen appeared as minute, round, viscid, pearly, white spots, measuring in the depth from about .4 to .5 mm. in diameter. The colonies in the depth under 3 objective are round or oval, yellowish in color and present nothing characteristic. After 5 days in the incubator at 37° C., the surface colonies were round, moist and viscid and slightly raised, some measuring as much as 1 or 2 mm. in diameter, and having a slight bluish refraction.

After two weeks these colonies had grown to no perceptibly greater size. Under 3 objective the margins of these colonies are smooth or more often undulating; the colonies are yellowish with a lighter periphery, and towards the center present a granular appearance; they are often nucleated. Cover-slips from a number of these colonies revealed a small coccus, occasionally in pairs but generally singly, and measuring about 3 mm. in diameter in stained specimens; this coccus completely decolorizes by Gram's solution. In hanging drop cultures very active molecular movement may be seen, but no independent motility. Inoculations from several of these colonies were made on various culture media with the following results:

On agar slants no growth is visible until the third or fourth or in some cases until the fifth day; the growth then occurs as a very faint one along the track of the needle, or as minute, pearly, white colonies. Old agar cultures sometimes show a yellowish color.

In bouillon no change is apparent for about two days, on the third day the medium is often slightly cloudy; this cloudiness gradually increases and there is eventually a slight sediment at the bottom of the tube. Cover-slips from this medium show the coccus in clumps and sometimes in short chains.

In litmus milk there is no change after one week.

In glucose-agar there is no gas production.

On blood-serum there is faint growth after 4 days.

In Smith's sugar-free bouillon there is no indol production.

On potato, after one week, there is apparently no growth. Gelatin tubes are not liquefied; the growth is very slow and delicate.

INOCULATION EXPERIMENTS.

1. One cc. of a suspension made with sterile salt-solution and a 5 days' old agar culture was injected subcutaneously into a strong, full-grown, healthy monkey, whose temperature for the week previous to inoculation had not been above 100° F. On the third day after the inoculation the temperature started to rise, and on the fourth day it reached 104.4° F. For the next 6 weeks the temperature varied, generally between 102° F and 104.6° F., reaching on one occasion, the seventeenth day after inoculation, 105.4° F. At the end of 6 weeks the last temperature recorded reads 102.4° F. After this date no record of the temperature was kept; the animal during the period of its fever seemed, at times, quite sick, and ate very little food; it eventually recovered. On the twelfth day after inoculation, the blood-serum of this animal in dilutions of 1 to 100, showed a marked agglutination of the organism obtained from the human spleen at the necropsy. The reaction of this monkey's blood was repeatedly tried at intervals with the same result during the next several weeks.

On the twentieth day after inoculation the monkey's spleen was aspirated, and 5 plate agar cultures made from the aspirated blood. On the fifth day of incubation all the cultures but one showed typical colonies. The organism obtained from these colonies agreed in all its peculiarities, both cultural and morphological, with those of *Micrococcus melitensis*. The bacteriologic notes from our laboratory animal book read as follows: The colonies are pinpoint to pinhead-sized, whitish and dew-like. Under objective 3 they are often nucleated, yellowish in color, with a darker periphery. In the depth the colonies are round or oval, and sharply circumscribed. Several of these colonies are planted on all media, with the following results: On agar-agar slants, after 3 days there is a very delicate, faintly bluish-white

growth. On glucose agar, a moderate whitish growth along the needle track is visible on the fourth day. There is no gas-formation. In fresh potato there is no apparent growth. Litmus milk and ordinary milk are not changed. Bouillon is clouded. A whitish sediment forms after 6 days, but no pellicle. In Smith's sugar-free bouillon there is no indol production. The organism obtained from these cultures is a coccus or short coccobacillus which completely decolorizes by Gram's solution. It also agglutinates with the monkey's blood-serum in dilutions of from 1 to 100 within one hour. The reaction is marked.

2. A full-grown, healthy monkey, whose temperature had not been above 99.8° F. for 4 days, was inoculated subcutaneously with 1 cc. of a 5 days' agar culture, suspended in salt-solution. On the evening following the day of the inoculation the temperature rose to 103.6° F. On the eighth day after inoculation it had reached 104.8° F. On this day the blood examination showed 17,000 leukocytes. On the tenth day after the inoculation the monkey died. At the necropsy the animal was found to be already somewhat emaciated. The spleen was considerably enlarged, swollen, and dark in color. The malpighian bodies were well marked. The mesenteric glands were enlarged and hyperemic. The liver-surface was smooth and presented a mottled appearance. The cut section showed cloudy swelling. The mucosa of the intestines was pale. The kidneys were congested and of a deep-red color. The other organs presented nothing abnormal. Blood-serum taken at necropsy shows a marked agglutination both with the organism obtained from the spleen of the human necropsy, and with the organism obtained from the aspiration of the spleen of monkey No. 1. The reaction is marked in dilutions of the serum of from 1 to 100 within one hour. From monkey No. 2, a coccus was obtained by plate cultures at the necropsy from the spleen, liver, and heart's blood, which agreed both morphologically and culturally in all ways with *Micrococcus melitensis*. It is also agglutinated with the blood-serum from monkey No. 1.

LABORATORY INFECTIONS WITH THE ORGANISM.

Since 1897 we have been able to find in the literature three examples of laboratory infection with *Micrococcus melitensis* occurring in human beings. These 3 cases reported by C. Birt and G. Lamb³ have proved conclusively that *Micrococcus melitensis* can produce Malta fever in man, and supplied the last link in the chain of evidence, viz: that this organism is the true etiologic factor of Malta fever.

The first case is reported as follows: In September, 1897, a man accidentally scratched himself with a needle of a syringe with which he had just injected into a horse a living growth of *Micrococcus melitensis*. The culture was derived from an agar slant taken two years before by Hughes from the spleen of a fatal case of Malta fever. He immediately sucked the wound, plunged the hand into 5% solution of phenol which he had by his side, and almost at once cauterized the puncture with pure phenol; but to no purpose, for on October 2, 15 days later, his temperature rose and he went through a typical attack of Malta fever. His blood-serum, in high dilutions, showed the agglutination of *Micrococcus melitensis* for one and a half years after.

The second case of inoculation in man occurred on March 1, 1897, when a man in connection with some experiments in the Army Medical Laboratory at Netley regarding the elaboration of a method of vaccination against Malta fever, injected into his arm one 1/100 of an agar tube of a seven days' growth of *Micrococcus melitensis*. The organism was derived from the same source as in the preceding case. On March 17, 16 days later, febrile symptoms set in and pursued a course characteristic of the fever. There was a marked increase in the polymorphonuclear leukocytes just before

the onset of the fever. The blood-serum showed agglutination of *Micrococcus melitensis* in high dilutions. Birt and Lamb also report a third case in which the patient contracted the disease in some way not known while he was working with the organism.

To this list we wish to add a fourth case of laboratory infection in which the portal of entry of the organism seems most interesting.

Cases of inoculation of infectious diseases in man, through the conjunctiva, are comparatively rare, although they have been reported in tuberculosis, gonorrhea, syphilis, diphtheria, splenic fever, and lyssa.⁴ During the operation of inoculating a monkey in regard to some immunizing experiments in this laboratory the barrel of the syringe became separated from the needle owing to the latter becoming momentarily clogged in some way, and some of the agar suspension of the organism entered the eye of one of us. The accident was commented upon at the time and the eye washed with water. Eleven days after this accident, the lower half of the left conjunctiva appeared acutely reddened and inflamed and later the lower lid became edematous and painful on pressure. A lymphatic gland at the angle of the left lower jaw became swollen and tender and a day later several other cervical lymphatics on the same side also became enlarged and painful. There was no sore throat and no tonsillitis present. The temperature rose by steps and reached 104° F. on the twelfth day. There was some sweating and excessive headache and neuralgia at times, but no other symptoms of note developed. The spleen was palpable. The blood-examination was negative for malaria plasmodia and for Widal's reaction; on the tenth day of the fever, the blood-serum showed a marked agglutination of *Micrococcus melitensis* in dilution of 1 to 60 in twenty minutes.

The fever gradually declined to normal at the end of the second month, after this there were only slight rises of temperature for a few days at a time. The blood-serum still shows marked agglutinating properties for *Micrococcus melitensis* in high dilutions.

GEOGRAPHICAL DISTRIBUTION.

Since the discovery of the microorganism of Malta fever by Bruce in 1887, cases of Malta fever have been reported in various localities. Wright and Smith,⁵ by means of the serum-sediment test, confirmed the fact that Malta fever is not confined to the Mediterranean basin. These authors tabulated 10 cases invalidated from India, in which the serum reaction gave a sedimentation value of an average of about 300-fold dilution; many of these cases at the time of the examination presented the usual sequels of the disease. C. Birt and G. Lamb (*loc. cit.*) report 10 other cases. These cases have been invalidated for such diseases as malaria, enteric fever and rheumatism; 14 of these 20 cases observed came from a comparatively small district station in the Punjab, viz: Meean, Meer; the other places in India where infection has occurred are Calcutta, Subathu, and Nowshera. One man contracted the disease in Hong Kong. This list may be extended by the following cases: Lieut. W. Glen Wiston, I.M.S., has reported a case contracted in Secunderabad in the Deccan, the serum from which gave a reaction in 80-fold dilution with *Micrococcus melitensis*. Musser and Sailer⁶ report the cases of an army officer who appears to have contracted the disease in Puerto Rico during the American-Spanish war. Malarial plasmodia were fre-

quently sought for, but never found. A culture of *Micrococcus melitensis* was agglutinated by high dilutions of the patient's blood. Kretz⁷ records the case of a physician who contracted an obstinate fever in Ajaccio, Corsica. This continued 6 months. After recovery his blood-serum agglutinated *Micrococcus melitensis* in dilutions of 300-fold. Birt and Lamb⁸ also report still another case which they state was evidently contracted in England, either in Plymouth or in London. The patient was sick from November, 1897, to March, 1898; there was edema of the feet, but the urine was normal. The edema lasted about a month and was succeeded by pain and swelling in certain joints. The hips, knees, ankles, left wrist and left temporomaxillary joints were all attacked in turn. After the disappearance of these symptoms left orchitis set in and lasted about a fortnight. Only during the period when the joints were affected was the temperature taken; at that time it was found to be about 102° F., in the evenings. The serum was not tested during the course of the illness, but was tried one year and two months after convalescence, when it was found to give complete sedimentation of *Micrococcus melitensis* in 20-fold dilution, and traces up to 50. The authors conclude that this was a case of Malta fever, contracted in either Plymouth or London, although no definite source of infection could be traced.

W. Cox⁹ reports a case of Malta fever in San Juan, Puerto Rico; the patient had 91 days of pyrexia with often marked daily remissions, with, at times, nearly a week of apyrexia, followed by fever again. The malarial plasmodia were sought for repeatedly, but not found; quinin had no effect on the temperature; Widal's test was negative with low dilutions; the blood showed agglutination of *Micrococcus melitensis* (1 to 60) in 25 minutes. Dilutions of 1 to 10, 1 to 20 showed marked reaction in 5 minutes. Cox thinks that Malta fever may be endemic in Puerto Rico. No case of Malta fever has been reported before in the Philippine Islands, though occasional references have been made in the literature to a long-continued fever occurring here. L. F. Atlee, who has lately left Manila,¹⁰ at the meeting of the College of Physicians, Philadelphia, December 6, speaks of an anomalous form of continued fever occurring here, which we think was perhaps Malta fever.

Since our first case, a second fatal case of Malta fever has occurred in Manila during the present month, the body having been received for necropsy from the Second Reserve Hospital; *Micrococcus melitensis* was isolated from the much enlarged spleen in pure cultures. This case will be reported in detail by Dr. J. J. Curry, U. S. A., at a later date.

Having convinced ourselves from our postmortem experience that Malta fever is not a very uncommon disease in Manila, we have begun to look about for these cases clinically, with the result that during the present week we have found three cases which give marked reaction with *Micrococcus melitensis* in high dilutions. One of these cases was diagnosed malarial remittent fever, though never could any malarial plasmodia be found in his blood, and he had had repeated attacks of fever while his pyrexia still persists. The other two cases were both diagnosed typhoid fever with relapse. Neither of these gave the Widal reaction nor were any malarial parasites present. Dr. J. J. Curry is now about to undertake in this laboratory a more careful study of the clinical cases.

REFERENCES.

- ¹ Since writing the above it is necessary to state that now, owing to the excellent arrangement of Dr. Hall, Major and Surgeon, U. S. A., commanding that hospital, blood-examinations are made in every case of fever admitted, and those patients in whom malarial organisms have been demonstrated are not allowed to return to military duty nor leave the hospital until their blood-examinations are negative for parasites. We may therefore hope from now on for more accurate statistics.

HISTORY OF A CASE OF REMOVAL OF A RETROBULBAR LYMPHOSARCOMA WITH PRESERVATION OF NORMAL VISION.¹

By CHARLES A. OLIVER, A.M., M.D.,

of Philadelphia.

Attending Surgeon to Wills' Eye Hospital; Ophthalmic Surgeon to the Philadelphia Hospital, Philadelphia.

On January 11, 1899, F. K., a weaver, 57 years old, applied at my clinical service at Wills' Hospital. He gave the following history: He was born in Germany. His health was good until 21 years of age. At that time a swelling termed a "goiter" by some government surgeons slowly developed in his neck. The enlargement became so great in size that he was rejected from military service. It was unaccompanied by exophthalmos, tachycardia, or any vasomotor symptoms and gradually disappeared in about 16 years.

He had a chancre on the glans penis 26 years before I saw him. This lasted some five or six weeks, and was repeatedly cauterized, but was not followed by any glandular enlargements, skin-eruptions, or alopecia. Six years after this he began to complain of occasional diplopia.

Many years ago, possibly about 20, he went to Wills' Hospital for glasses, though he does not remember the exact date of the visit nor the name of the attending surgeon.

In 1857 his eyes were examined by Dr. A. G. Heyl at the Hospital of the Protestant Episcopal Church in Philadelphia. Dr. Heyl informed him that "a small vessel which would eventually give him trouble was developing in his right eye."

He again sought advice at Wills' Hospital 12 years later and became a patient of Dr. S. D. Risley. Study of the notes of the case in Dr. Risley's records shows that vision in each eye was brought to practically normal by a convex spherocylinder lens placed before the right eye and a convex spherical lens before the left one. At that time he complained of an intense pain in the right side of the head and in the right eye. This, he said, dated back for some three weeks, and had been produced by catching cold. At that time tension in each eye was normal. The right eye was congested. Its cornea was sensitive, and its iris responded to light impulse and efforts for accommodation. The rims of the crystalline lenses were noted as being opaque, and there were four degrees of homonymous diplopia for distance.

For five years before I saw him, he had noticed a "ringing at night in the ears," this having gradually lessened. He never complained of dizziness.

Three years before his first visit he suffered from an attack of gonorrheal urethritis. A year after this he had a slight fall followed in six months' time by a prominence of the right eye. About three months before he came to the clinic he noticed that he could feel a swelling above the same eye.

He said that 8 days before he had applied to the clinic he had consulted Dr. T. B. Schneidemann of this city, who informed him that he was suffering from an orbital growth, and advised him to go to Wills' Hospital for operation.

A photograph taken when he was 20 years of age showed a swelling in his neck, which was more marked on the right side. There was not any appearance of exophthalmos. The palpebral fissures were apparently of the same size. Another photograph taken in a group some 18 years later was

unfortunately so positioned as to make the patient face the direct sunlight. In it some spasm of the left orbicularis palpebrarum associated with an elevation of the left angle of the mouth could be determined, both expressions probably having been caused by the impingement of the direct rays of the sun upon the parts. In a third photograph sat for only 5 or 6 years before he came to the hospital, the neck appeared normal. The right palpebral fissure was a trifle wider than its fellow, and there was no exophthalmos. A fourth photograph taken in a badly placed and too brilliantly lighted group some three years after the third one, exhibited a similar character of facial distortion as was seen in the second picture. In it there did not seem to have been any exophthalmos present.

At the time of the first examination it was found that the affected organ projected markedly forwards and downwards, its corneal summit being 6 mm. in advance of its fellow and 3 mm. lower. The conjunctival vessels, particularly the bulbar, were injected and swollen. Above the globe there was a rather deeply seated and freely movable mass of tissue giving a sensation to the finger-tips as though it were composed of a series of underlying swollen and twisted bloodvessels. At times, this tumor-mass seemed to pulsate synchronously with the aortic beat. Carefully repeated examination, however, failed to evidence any thrill, though an unmistakable bruit could be occasionally heard in the orbit and in the temporal region. There did not seem to be any projections or deformities in the osseous parts. Von Graefe's and Stellwag's signs were undeniably present.

The pupil of the affected side was 2.5 mm. in size, and oval, with its long axis at 80°. There were a number of equatorial striae in both the anterior and posterior cortices of the crystalline lens. The optic disc was 7 by 8 diameters in its apparent magnitude, and its long axis was situated at 80°. The edges of the disc were everywhere hazy, though a broad scleral ring with an absorbing conus beyond could be fairly well seen. The disc substance was dirty dull red-gray in tint and there was an eccentrically situated physiologic excavation. Both the retinal veins and arteries were much reduced in size, the former being exceedingly tortuous. The usual light streak along the vessels could not be determined after most careful examination. There was not any spontaneous arterial pulse, though a slight venous pulsation could be determined at times. The choroid was quite granular, but did not evidence any signs of gross inflammation. There was a marked astigmatism, the fine retinal vessels at the long axis of the disc being most plainly seen with a convex lens of five diopters' power.

The pupil of the left eye was the same size as its fellow, its long axis being at 70°. With the exception of a few striae in the anterior and the posterior cortex of the crystalline lens, the media were clear. The optic nerve head was 7 by 8 diameters in apparent size, with its long axis situated at 80°. There was a broad scleral ring to the outside of the nerve head with a narrow one in. Annular pigmentation could be plainly seen. The currents of the retinal arteries were somewhat narrowed, although the retinal veins were not tortuous. The ordinary light streak along the main retinal vessels was quite manifest.

The iris of the left eye reacted more freely to light-stimulus and accommodation than its fellow, while varying degrees of exophoria during both near and far vision could be determined at times; particularly in the lower portions of fields of vision.

Uncorrected vision with the right eye equalled about $\frac{1}{2}$ of normal, while that with the left was $\frac{1}{4}$. Both the accommodative regions and powers in each eye were proportionate to the character and the degrees of refraction error and age. There was a marked astigmatism with hypermetropia and presbyopia.

The fields of vision for white, red, and green were normal. The field of fixation was quite large and well shaped.

General physical exploration and study of the blood made by Dr. Joseph Sailer, of Philadelphia, was practically negative. There was not the slightest evidence of any gross organic disturbance, the signs of Hodgkin's disease being most carefully and assiduously sought for. Dr. Sailer's report in full is as follows:

"Muscular system well developed. Skin sallow. Mucous membranes good color. No scars or marks upon the body. None of the lymphatic glands can be palpated

¹ Read before the American Ophthalmological Society at the Fifth Triennial Meeting of the Association of American Physicians and Surgeons, May, 1900.

through the skin. The spleen is apparently large in size. The liver can be felt one finger's breadth below the border of the ribs and extends above to the sixth rib. The heart-dullness commences superiorly at the upper border of the fourth rib at the mid-sternum and passes to one inch to the right of the left nipple line. The apex beat is indistinctly felt in the fifth interspace in the nipple line. On auscultation there is a reduplication of the first sound at the apex, which persists with a slight roughness as the stethoscope is placed at higher levels. The second sound is somewhat roughened in the third interspace. The second aortic sound is louder than the second pulmonic. The first sound in the fifth interspace to the right of the sternum is loud, clear and resonant.

"There is distinct pulmonary expansion at the liver border although posteriorly, at the apex, no expansion can be felt by percussion. On auscultation there is prolongation of the expiration at both apices. This is less distinct towards the base; otherwise the pulmonary sounds are clear.

"By percussion there appears to be a mass giving a tympanic note extending two inches below the ribs of the left side, and about one inch to the right of the median line, which probably represents the stomach. Palpation and percussion of the abdomen is otherwise normal.

"There are no pareses nor any gross disturbances of sensation. The right bicipital and corresponding tricipital reflexes are slightly increased. There is considerable myotonic irritability. The tendon-reflexes of the left arm cannot be elicited, though the myotonic irritability is similar to that on the right side. The thoracic and abdominal reflexes are prompt. The cremasteric reflex is very pronounced on both sides. The kneejerks are exaggerated. There is a distinct patellar tendon-reflex on each side. The Achilles tendon-reflex cannot be distinctly obtained. There is no ankle-clonus.

"Examination of the blood shows that the red blood-cells are of normal size and shape, and stain distinctly. There is about a normal proportion of white blood cells with the following differential count: Polymorphonuclears, 64%; small lymphocytes, 29%; large mononuclears, 5%; and degenerated cells about 2%. No eosinophilic or basophilic cells were present."

Both chemic and microscopic examination of the urine failed to reveal the presence of anything abnormal in this excretion.

In other words, aside from a slight alteration in the heart, which was probably due to a commencing atheroma of the valves, and an emphysema of the apices of the lungs, the general physical examination was negative.

After a fair trial of medicinal agents, including the administration of large doses of arsenic, I performed the following operation for the removal of what I felt certain was a postocular growth. A circumlinear incision following the line of the upper orbital margin and extending nearly the entire length of the superior palpebral fold was made in the upper eyelid just above its sulcus. The underlying tissues were freely dissected until the finger tips could be gotten into the extraocular muscle cone, care being taken to avoid injuring the fibers of the levator muscle.

In this position a multilobular mass which was composed of four distinct parts could be plainly felt. The largest lobe extended into the upper inner angle of the orbit, and the entire mass was connected with a peduncle which arose from the outer side of the lobe outside of the funnel, and passed directly back to the apex of the orbit.

These masses were extirpated by means of the finger tips, scissors, and flushings of 1 to 4,000 bichlorid of mercury. The operative field was freed from all useless and ragged tissue, cleansed, and dried. The surface-wound was coated with 6 superficially placed iron-dyed black silk sutures. The conjunctival sac was cleaned with sterile water and a few drops of a 1% solution of atropin were dropped on the corneal surface. The field of operation was covered with a single figure-of-eight gauze bandage. The patient was placed in bed and iced compresses were applied on the bandage for the first 24 hours.

The specimens were given to Dr. Edward A. Shumway, in charge of the Eye Department of the Pathological Laboratories of the Philadelphia Polyclinic and School for Graduates in Medicine.

The stitches were removed on the second day, and as there had not been any postoperative reaction, the patient was given indoor liberty. A marked ptosis with almost complete want of action of the palpebral levator ensued, while examination of the extraocular muscle-balance at this early period showed but a 2.5° of exophoria at 6 meters' distance. Corrected vision in each eye was almost normal. In 10 days' time the ptosis had somewhat diminished, the patient being able to lift the upper lid some 2 or 3 millimeters. In less than a month, without the employment of any form of treatment, the eyelid operated upon could be kept lifted so well that its ciliary border was kept almost constantly on a level with that of its fellow—the closest scrutiny being necessary to distinguish any difference between the widths of the two palpebral fissures.

Examination of vision and refractive error, 4, 8, and 12 months later, gave normal results. The double vision had been quite persistent and most variable, necessitating at first, though at present to a much less degree, the employment of a shade before one eye during any attempts for near work.

At present writing, nearly 18 months after the operation, there has not been any return of the growth, the patient being well, and daily employed at his livelihood.

The pathologic and microscopic report of the orbital growth was practically as follows:

The specimens which exhibited similar macroscopic appearances consisted of 6 pieces, 2 of which were large and 4 small. The large ones were evidently a part of one mass. Together they measured 4 cm. in length, by 2½ cm. in breadth, and ½ cm. in thickness. They were imbedded in celloidin, and the sections were stained with hematoxylin and eosin.

Examination with the microscope showed the tumor to consist mainly of a dense mass of closely-packed, round, fascicular nuclei. The cell-bodies were indistinct. In places there were broad bands of connective tissue that stained deeply with eosin. In some portions of the growth aggregations of large endothelial cells with distinct protoplasm and pale, round or oval nuclei could be seen. Many of these were associated with bloodvessels, though in a few situations they were collected into clumps without the presence of red blood-cells. The vessel-walls were somewhat thickened and exhibited a tendency to hyalin change. There were neither aggregations of true lymphocytes nor evidences of karyorrhexia in the nuclei.

A carefully conducted detailed local and general re-examination of the patient at the present writing fails to show the slightest evidence of any local return of the growth or the least appearance of any metastasis. With the exception of an almost infinitesimal degree of nondisturbing diplopia in the lower field of vision during near-work, the gross local signs have ceased. The patient is apparently healthy in every respect and is employed many hours daily as a weaver.

Remarks.—This case is one of some interest. Occurring in a goitrous subject free from any other sign of Hodgkin's disease, and with the history of acquired syphilis, the tumor furnished the ordinary symptoms of exophthalmos with bulbar displacement; mechanical and functional limitation of mobility of the eyeball; diplopia; contraction of the retinal arteries; and engorgement of the retinal and conjunctival veins. In fact, most, if not all, of the pressure-symptoms of a retrobulbar growth.

The tumor successfully extirpated without injury to the eyeball or its functioning power, merely giving rise to temporary disturbance of the contiguous

muscular structures, serves to illustrate the average results of ophthalmic surgery of today.

The findings of the microscope, which necessarily are indeterminate as to such growths being truly sarcomatous or lymphomatous in character, taken into consideration with the multilobular nature of the mass, distinctly point to its being a lymphosarcoma.

The lapse of time since the removal of the growth without the least signs of any local or metastatic expression of the former disease, although, of course, of too brief a period for any certainty of conclusion, is of much importance in showing that the growth was not malignant in character, while the return of the organ to its original healthy condition is a result which must be considered as most fortuitous.

TRAUMATIC ANEURYSM OF THE LEFT INTERNAL CAROTID ARTERY: DEATH: AUTOPSY.¹

By BURTON S. BOOTH, M.D.,

of Troy, N. Y.

On January 18, 1900, I was asked by Dr. H., of Hoosick Falls, to see Mr. P., a Dane, aged about 25, who lived in the suburbs of that village. He informed me that Mr. P. had been treated by other physicians before he consulted him, and all had supposed the man to be suffering from "chronic quinsy" of the left tonsil, which had necrosed into the walls of an artery, causing hemorrhage from the nose and throat. The hemorrhage was so severe and frequent as to be alarming. My first examination was made January 18, 1900, in the afternoon. I found him very anemic, with a pulse of 120 per minute, and temperature about normal. I also noticed a fetid odor from the breath, very penetrating in character. On making inquiries I found that Dr. H., of Troy, had tamponed the right nostril from behind, and that in some way the string which was attached to the tampon for its removal had been torn away, leaving the tampon in the right nostril since January 16, it being impossible to remove it. On superficial examination I was convinced that the man was suffering from some grave disease, and advised his family to send him to the Troy Hospital, where he could receive proper attention. This they did the same day, and on January 19, the next day after his admission, I was able to obtain the following history:

His mother died of pulmonary tuberculosis, otherwise his family history was negative. Patient had had usual diseases of childhood, measles, diphtheria, and scarlet fever. He was deaf for one year after the latter disease. His tonsils were removed when he was a small boy. About two years ago, while coasting down a hill on a bicycle, he collided with a man and was badly injured about the face, his nose being broken; he expectorated blood for some time after this accident; he also informed me that he prided himself on his strength, and often tested it severely. Present trouble began January 1, 1900; he thought he had taken cold and sent for the doctor, but was not benefited by treatment; he began to have hemorrhages from the throat and nose, and these attacks of hemoptysis and epistaxis continued, and grew more frequent, occurring almost every day, treatment having little effect.

Examination revealed that the patient was poorly nourished and very anemic, skin waxy, dry, and did not appear to be quite as elastic as usual; circulation poor, pulse ranging from 92 to 120, temperature from 98° to 101°, respirations from 20 to 24 per minute. Examination of chest showed emphysema of the lungs, hypertrophy of the right side of the heart, and a systolic murmur over the pulmonary valves; examination of abdominal organs negative. Slight ptosis of the left upper lid and contraction of the left pupil was present; urine was slightly turbid, light straw in color, strongly acid, specific gravity 1.021, no albumin, no sugar; microscopic examination negative.

Examination of Blood.—Hemoglobin, 50%; red blood-corpuscles count, 1,010,000. There also existed a leukocytosis of 16,000.

Examination of the nose anteriorly revealed a deviation of the septum to the right, a purulent offensive discharge from both nostrils, a posterior rhinoscopy revealed the tampon (which had been in place 3 days) occupying a position in the right nostril, just behind the convex portion of the deviated septum close to the floor of the nose, also purulent discharge.

Examination of the pharynx revealed a mass occupying the left tonsillar region extending into the median line filling the left half of the nasopharynx to the vault extending down into the lower pharynx as far as could be seen. In the center of the mass high up in the nasopharynx a hemorrhagic spot about 4 mm. in diameter could be seen. Laryngoscopic examination revealed nothing except a slight hypertrophy of the lymphatic tissue at the base of the tongue.

January 23, the case was referred to Dr. Adt for an examination of the eyes and he reported as follows: I found a sympathetic paralysis involving the left eye, the result of pressure upon the carotid plexus which surrounds the internal carotid artery. There is a slight ptosis on this side, the result of paralysis of Müller's muscle; also a contracted pupil, a myosis due to paralysis of the dilator of the pupil; the pupil reacted to light and no vasomotor disturbances could be detected.

On January 20, the day after admission into the hospital, the patient was anesthetized and the tampon was removed from the right nostril, it being necessary to push the deviated septum into the opposite nostril and the plug into the nasopharynx by means of the little finger. A small piece from the mass in the left tonsillar region was removed at the same time and submitted to Dr. Blumer, who reported that it was inflammatory tissue and that there was no evidence of malignancy.

The patient was kept quiet in bed on a light diet. He complained of no pain in the throat and appeared to feel fairly comfortable except that on January 25 he complained of pain in the bowels. January 26 he had a hemorrhage from the nasopharynx and vomited 500 cc. of clotted blood, January 28, at 9 p.m., he had a slight hemorrhage from the nasopharynx which was controlled by ice. January 29, 9.15 a.m., he was taken with profuse hemorrhage from the mouth and nose which proved fatal in a few seconds.

Diagnosis.—Dissecting aneurysm of the internal carotid artery.

Dr. H. O. Fairweather made an autopsy the same day the patient died and reported as follows:

Autopsy done at Troy Hospital 5 hours after death. Body of Jacob P., aged 25 years, laborer, Hoosick Falls, N. Y. Body about 165 cm. in length, strongly built and well nourished. There are no marks or bruises about the body and no evidence of subcutaneous edema. Rigor mortis well marked, also postmortem lividity of the dependent parts.

Upon any attempt to move the body, particularly the head, there occurs a profuse discharge of dark-colored blood from the mouth and nasal cavities. The abdominal cavities were not examined, but the autopsy consisted in the dissection of the larger bloodvessels from their origin in the arch of the aorta and especially in the dissection of the common and internal carotid arteries. On section the subcutaneous fat is moderate in amount and the muscles are fairly well developed. Costal cartilages are not ossified. On exposing the arch of the aorta, the dissection of the left common carotid was begun and this followed up to its division into the external and internal carotids. From this point the internal carotid was followed to its point of entrance into the canal in the petrous portion of the temporal bone. At a point in the internal carotid, about the junction of the cervical and petrous portion was found an aneurysmal sac. This had an approximal diameter of 2 cm. and its wall was about the thickness of membrane. The sac had ruptured and there was marked hemorrhage into the surrounding tissues. Heart: The pericardial sac contained a moderate amount of fluid. No adhesions to the heart-wall. The organ was apparently normal, excepting perhaps a slight thickening of the wall of the right side. The valves were apparently normal. The aorta showed some atheromatous

¹ Reported at the meeting of the Section on Laryngology and Rhinology of New York Academy of Medicine, May 23, 1900.

patches and calcareous deposits in a small area just below the arch. Anatomic diagnosis: Rupture and subsequent hemorrhage of an aneurysmal sac situated about the point of junction of the cervical and petrous portions of the internal carotid artery.

I report this case because of its being uncommon to find an aneurysm in this location. The condition might easily have been mistaken for a peritonsillar abscess.

From the history it will be observed that a slight rent existed in the aneurysmal sac for some few days prior to the death of the patient, and that the hemorrhage he suffered from on several occasions was due to this cause, and had it not been due to the tortuous course which the blood took before finding its way into the nasopharynx the patient would have died long before he did. I might say that had I manipulated the nasopharynx very much in removing the plug from the right nostril I might have ruptured the aneurysmal sac with disastrous results.

There is no doubt but that the origin of this aneurysm dates back to the accident he had two years ago, and that the external coat of the artery was ruptured at that time, and the custom of testing his strength, as he explains in his history, had a tendency to hasten its formation.

In closing I might briefly summarize the symptoms which were present:

1. The mass on the left side over the course of the internal carotid completely filled the left nasopharynx, tonsillar and the lower pharyngeal region, extending into the median line; the mass appeared to be uneven and dark-red in color, and showed the hemorrhagic spot from where the blood was oozing.

2. There was no apparent pulsation.

3. The mass appeared hard and firm to the touch.

4. The patient did not complain of pain.

5. The frequent hemorrhages from the nose and mouth.

6. The sympathetic paralysis involving the left eye, the result of pressure—a symptom not to lose sight of, as I am led to believe that this symptom is often present in tumors involving this location.

7. The diminution of the red blood-corpuscles and hemoglobin and the presence of the leukocytosis were also interesting features of the case.

A NEW ASEPTIC ETHER AND CHLOROFORM INHALER.

By ERNEST LAPLACE, M.D.,

of Philadelphia.

Professor of Surgery, Medico-Chirurgical College.

THIS inhaler, devised by myself and in use over a year in my clinic, consists of two oval cones, joined by a hinge and fastening with a clasp. The inner cone is

FIG. 1.—Inhaler open. Inner view.

made of wire netting and the outer cone is of solid metal, in the center of which is an opening shaped like a cross. A sufficient amount of ordinary sterilized gauze or cheese-cloth is placed between the two cones. The apparatus fits the face. Ether is poured upon the gauze through the cross-like opening of the outer cone,

FIG. 2.—Inhaler closed, and empty.

and evaporates through the inner cone of wire netting. A smooth metal trough surrounds the base of the inner cone to receive any surplus of ether.

Should chloroform be administered, only a small amount of gauze is placed between the cones. This will permit free circulation of air.

FIG. 3.—Inhaler filled with sterilized gauze, and ready for use.

The advantages of this inhaler are:

1. It is simple, compact, and sterilizable by heat.
2. It is instantly and easily prepared for use.
3. It is always clean. The ether does not come in contact with the patient's face at any time. The gauze is changed for each patient.
4. It is adapted to both ether and chloroform.
5. There is a marked economy of ether.

This inhaler was shown by me at the International Medical Congress in Paris, August 6, 1900, and was presented to the County Medical Association, of Philadelphia, October 10, 1900. It is made by the Kny-Scheerer Co., 17 Park Place, New York.

A NEW PHIMOSIS FORCEPS.

By W. T. BAIRD, M.D.,

of Fort Bliss, Tex.

Acting Assistant Surgeon U. S. Army.

THE new "circumcision forceps" described, which I have had made for my own use and have been using for the past six months with a great deal of satisfaction to myself and the infinite delight of my patients requiring this class of work. The forceps fulfils in a high degree the object for which it was intended, that is, to facilitate the operation, and divest it of most of its disagreeable features, so that it may not be dreaded by the patient, but, on the contrary, may be the means of inducing him to cheerfully submit to it when otherwise he would not.

In the use of this instrument, the operation consists

of three hypodermic injections of a 4% to 6% solution of cocain, which, in the manner in which it is used, secures perfect local anesthesia (thus eliminating in all cases the dangerous and disagreeable effects of general anesthesia)—three incisions—the introduction and tying of the sutures—and the final dressing.

First Step.—Inject a few drops of the cocain-solution into the prepuce on a line directly over the center of the dorsum of the glans, as far up as the corona. In about a minute, divide the prepuce along this line, with a pair of scissors or scalpel, as far up as the corona, being guided by a grooved director.

Second Step.—Grasp the prepuce lightly (so as not to cause pain) on the right side (or left, if preferred) with the forceps, the concave border encircling and closely hugging the penis, and carefully coaptate the edges of the skin and mucous membrane where they were divided by the incision. Now inject a sufficient quantity of the cocain-solution along the convex border of the blades to secure perfect freedom from pain, next grasp the handles and close the blades firmly—then with scissors or scalpel sever the prepuce close along the convex border of the blades as far around as the frenum, and there let it remain for the time being, while the sutures are passed through the needle-guides with a straight needle carrying a fine catgut-suture, and tied.

Third Step.—Unclasp the forceps, grasp the flap on the other side, coaptate the edges carefully, inject the co-

cain, and complete the operation as it was done on the opposite side. The forceps are now unclamped and laid aside. It is generally necessary to insert a suture (and sometimes two) at or near the upper point of the first incision.

When the operation is completed, no uncovered points or surfaces should be seen, but the coaptation of skin and mucous membrane should be perfect. The instrument is made of the very best of steel, and so constructed that the two blades along their convex border are a perfect fit when the handles are closely approximated, and thus close the extremities of the severed vessels so thoroughly that, in the time occupied in the adjustment of the sutures, the blood in them is firmly coagulated, and therefore no hemorrhage can occur after the part is released from the grasp of the forceps.

Also, the perfect coaptation of the blades prevents the cocain from entering the general circulation, and thus serves as an effectual safeguard from any danger from that source.

The inner or concave border of the blades do not meet when they are firmly clasped by about three millimeters, and thus pressure anemia is prevented, and consequent inhibition of repair.

I now use in all cases a gelatin dressing, which I prefer on account of its being cleanly, nonirritant, elastic, thoroughly protective, and one which the patient can wear without changing until repair is complete.

I have it put up as follows:

R.—Zinc oxid.....	2 grams.
Formalin (1% solution).....	2 grams.
Gelatin	4 grams.
Glycerin	6 grams.
Aqua dest.	8 grams.

Dissolve the gelatin in the water for several hours, then add the zinc and glycerin—previously mixed—by the aid of heat. Don't boil—heat before using, apply with a small spatula.

I then complete the dressing by using plain, sterilized gauze, leaving the meatus free, and securing the organ in an upright position by a bandage passed around the body.

I have in this manner circumcised 30 cases, 15 of them for gonorrhea, acute and chronic. The average time which these gonorrheal cases were off duty and under treatment, was 15 days, as shown by the hospital register, as against an average of from 40 to 45 days in cases retaining the elongated prepuce. (These cases were also treated with injections of a mild solution of permanganate of potassium.) One of my last cases was a private in the Hospital Corps, and as soon as he arose from the table he went to the stable and harnessed a horse to a buggy and drove a mile on an errand, and after that he never missed an hour's duty, and he was entirely well in 5 days. He was not required to do duty during this time, but did it of his own free will and accord, and without once complaining of pain or inconvenience. In from 3 to 5 days, I remove the dressing by soaking in warm water, and if any unhealed points are seen, I renew it and let it remain a few days longer. In all cases, after the dressing is first adjusted, the patient is allowed to go about as he pleases, and in no case is it necessary to confine him to his room or bed. It may appear to you as though I am carelessly asking too much space in so minutely describing such a trivial operation as circumcision, but if you could fully realize how much the operation is dreaded, as usually performed, and the immense number of those who are constant sufferers for the want of the operation, and then could see the cases which come to me urgently soliciting the operation by this painless method, you would freely forgive me for urging it.

For the sake of convenience, it is well to have three sizes—one for infants, another for youths, and one for adults.

However, with a little additional care, I have very successfully used the adult's size on both infants and youths. These instruments are now manufactured by the Kny-Scheerer Co.

Surgical Treatment of Peptic Ulcer.—Wenner (*Cleveland Journal of Medicine*, October, 1900) says that Mikulicz reported the first operation for relief of hemorrhage from peptic ulcer in 1880. Various authorities agree that between 4% and 5% of persons dying from all causes have at some time during their lives suffered from peptic ulcer. A record of 10 817 autopsies showed the presence of an open ulcer in 1.5% of the cases. A report of 187 cases occurring in the Massachusetts General Hospital gives 64 as the percentage of cures, and 36% of these relapsed. Perforation varies, according to different authors, from 1.3% to 3.2%. The author has collected the reports of 42 cases operated upon, with 24 deaths, or a mortality of 57%. From a study of these cases he comes to the following conclusions: (1) The severity of the hemorrhage does not indicate the degree of ulceration; (2) the time of vomiting bears no constant relation to the location of the ulcer; (3) repeated small hemorrhages or recurrence of a second grave hemorrhage demands operation; and (4) after careful medical treatment, extending over a period of 2 months, without amelioration of symptoms, an operation should be advised. [A.B.C.]

Newspaper Pathology.—The present illness of the Czar of Russia furnishes many opportunities for the newspaper scribes to air their ignorance of the very elements of the science of pathology. His Russian Majesty is reported by his physicians to have a mild attack of typhoid fever. The bulletins have indicated the accuracy of this diagnosis. On the 25th the temperature rose to 103° with a pulse of 88, and the general condition was good and without complications. With such a report from authoritative sources the public, one would think, would be content to accept the diagnosis and await patiently for the next bulletin. But this is not the newspaper's way. According to one paper, for instance, the Czar had not only typhoid fever but also pulmonary tuberculosis and traumatic meningitis, all in one paragraph. Surely all this is enough to kill even an emperor.

The phraseology of the newspaper pathologists is also extraordinary. In the case of a U. S. Senator, who most unfortunately has been suffering from blood-poisoning, we were told recently that his "invincible will-power" was the only thing that kept him alive. As the patient was delirious half of the time, we fail to see how his "invincible will-power" could act to advantage, and even if he were not delirious we cannot understand how an "invincible will-power" can act as an antitoxin to the blood-poison that is threatening life. The newspaper pathologist should mount to a higher plane.

The Transmission of Bovine Tuberculosis to Man.—An attempt has been made on the part of some to establish a differentiation between the tubercle-bacilli of man, of cattle, and of birds, respectively; but the evidence seems to point to their identity, such differences as may be apparent being attributable to variations in environment. The formation of a definite opinion in this connection is of great importance, inasmuch as in accordance therewith will steps be taken to prevent infection among the three groups of animals mentioned. To the evidence already existing in favor of the identity of the tubercle-bacillus of man and that of cows, M. P. Ravenel (Proceedings of the Pathological Society of Philadelphia, October, 1900, p. 259) adds the report of three cases of cutaneous tuberculosis in human beings resulting from inoculation with the bovine tubercle-bacillus. All occurred in veterinarians,

who received wounds of the hands in the course of postmortem examinations of tuberculous animals. In the first, a nodule developed, with a tendency to ulceration, after infection by a tuberculous cow. The growth was removed and on section presented the histologic characters of tuberculosis, although tubercle-bacilli could not be demonstrated satisfactorily. In the second case the lesion was acquired in the course of postmortem examination of a goat dead of experimental inoculation with a culture of the bovine tubercle-bacillus. A nodule formed and was excised, and a portion, examined histologically, exhibited an infiltrating process encroaching on the papillary layer of the skin, and destroying some of the papilla. With the remainder two guineapigs were inoculated subcutaneously, and several weeks later both exhibited generalized tuberculosis involving the chest-cavity, as well as the abdomen. In the third case, in which the tubercle resulted from infection by a tuberculous cow, the growth was removed and tubercle-bacilli were found in sections.

Tuberculosis in Pennsylvania.—If in any one year the commonwealth of Pennsylvania lost 8,000 inhabitants from cholera or the plague, there would occur such a panic that the State would be partly depopulated, and many of its industries paralyzed. Yet the State of Pennsylvania loses every year about 8,000 of its citizens from tuberculosis, and these citizens are nearly all in the prime of life. So true is it that familiarity with danger breeds contempt. But surely it is as distressing for people to die of the one disease as of the others. Tuberculosis is, or ought to be, as frightful as plague in one sense; in fact, it is more frightful, for plague is only a sporadic visitor anywhere, while tuberculosis is with us all the time.

In an instructive paper read at the last meeting of the American Medical Association, Dr. Guy Hinsdale (*Journal American Medical Association*, October 20) presents the subject of tuberculosis in this State in a graphic and intelligible way. We are particularly struck with the significance of the figures of the disease in Philadelphia. Between 1870 and 1897 there was a constant fall in the number of deaths from pulmonary tuberculosis in proportion to the population, but the proportion rose slightly without apparent cause in 1899. In 15 years the percentage of deaths had fallen from 14% of all deaths to only 10%. The recent slight rise

in the percentage may be due, as suggested by Dr. Hinsdale, to the improved laboratory technic with which tuberculosis is now studied. This explains also the decrease in the number of deaths from bronchitis. These cases are now diagnosed more accurately. In spite of this improved technic, however, there were only 1,434 deaths from tuberculosis for the first six months of 1900 as compared with 1,507 deaths for the same period in 1899. Considering the zeal with which the tubercle-bacillus is searched for at present, this is a gratifying showing.

The gist of Dr. Hinsdale's paper is in the suggestion he makes for a State hospital for consumptives. Appeals have been made, so far without result, to the State legislature to provide for a hospital or sanatorium, to be erected in some mountain region suitable for the purpose. These measures have been "sympathetically" received by the committee on appropriations—but they have not been so sympathetically acted on. Politics and economy are somehow in the way. In the meantime the great white scourge keeps right on with its work in Pennsylvania, and the State legislators may yet have to answer to an awakened public opinion; for that public opinion is being gradually awakened and enlightened on this subject of tuberculosis is abundantly proved in Dr. Hinsdale's paper. In this State, the Society for the Prevention of Tuberculosis is doing genuine missionary work by distributing tracts and otherwise promoting a campaign of education. There are already some small but deserving hospitals devoted to the care of consumptives, but in the main, as Dr. Hinsdale says, Pennsylvania, and America too, is behind such countries as England, Germany, and France. In the name of the 8,000 annual victims of tuberculosis, let the legislature of Pennsylvania awake.

The treatment of tuberculosis is one of the approaches of the medical profession. It is an infectious disease due to a microorganism whose characteristics are so well known, and of such a nature, as to render its destruction outside the body not a matter of extreme difficulty; nevertheless, in certain situations in the human body it proves to be one of the most intractable of all the infectious agents.

Obviously there are three methods of combating the disease: First, the removal of the infected tissues. This is readily accomplished by surgical measures in many of the forms of tuberculosis, as, for example, in scrofulous glands, and not infrequently the cure is permanent. Second, the destruction of the bacillus in the diseased tissue. It is possible that this is the method of cure in cases of tuberculous peritonitis; however, it is quite unknown how it is accomplished. Finally, the stimulation of the tissue to resist the action of the microorganism. For this purpose we have a varied assortment of serums, limited, apparently, only by the number of bacteriologists, or pseudobacteriologists, who have un-

dertaken to make their fortunes by imposing upon the credulity both of the profession and of the laity. None is certainly useful, and improvement, after the use of a few has been observed only when the surrounding hygienic conditions were favorable. Various drugs have been employed; tonics, stimulants, and expectorants; of these, creasote and its derivatives have attained the most general favor, but even the most enthusiastic advocate does not claim for them more than a minimum curative action. One procedure alone seems to be effective, and to be useful not only in the early, but, to a certain degree, in the later stages, in combination with rest and nutritious diet; this is, of course, the open-air treatment. It has been customary in the past, to send those patients whose financial conditions would permit, to the woods, or to high altitudes, and to place them under the most favorable hygienic conditions, and this plan, as a rule, has worked admirably. Unfortunately it is of no avail for the poor, who refuse, or are unable to afford, proper hygienic surroundings in the incipient stages of the disease, and who, only when compelled by increasing weakness, seek an asylum in some hospital that will receive them. Here in Philadelphia there is only one general hospital that does so, the Philadelphia Hospital. Unfortunately, coming as do patients in a condition frequently hopeless for cure, in many instances they are more or less neglected, the chief precaution being the prevention of infection of other inmates. These precautions are admirably carried out, but the mortality among the consumptives is alarmingly high, and although most of them manifest a temporary improvement as a result of proper clothing and food, the progress of the disease is unchecked. Now it has been shown, particularly in Germany, but also in certain places in this country, such as Boston, that the essential feature of the mountain cure is less the altitude than the fresh air, and that even in the smoky atmosphere of our cities, persistent life in the open air is of benefit. This has been tried to a very limited extent in Philadelphia, and the results have been gratifying. Why would it not be possible, therefore, to erect, in connection with some of our hospitals, pavilions, open on four sides, but with roofs to shelter the inmates from rain and snow, in which tuberculous patients could spend the greater part of their time, thoroughly wrapped up and protected from cold, but breathing fresh air continuously? If such a well-recognized procedure could be called an experiment, it could be carried out very cheaply. Such a pavilion need not cost more than a few hundred dollars, even if designed to accommodate several hundred persons, and the improvement that would accrue to the patients, not only on account of the fresh air, but also because of the added interest that would be taken in their condition, would be so pronounced that it would far outweigh the slight initial expenditure, and perhaps a greater amount of wear on the blankets. Otherwise the cost would not

exceed that at present required for the care of the patients in the wards.

We earnestly recommend the consideration of this suggestion to the various hospital boards, and particularly to the officials of the city of Philadelphia.

The healthfulness of large cities as compared to the conditions found one hundred years ago or earlier, has often been remarked of late and is greatly to the credit of the efforts of modern sanitarians, most of whom have been members of the medical profession. In a recent editorial article the *Lancet* (Nov. 3, 1900) comments on the service of the City Imperial Volunteers of London in the South African campaign. The work that was performed by the corps makes it clear that the young civilian of the present day, though his occupation be mainly at desks, is a man of fine physique and well-developed powers of endurance; in fact, is as capable in every way of taking the field as any country-bred lad brought up to open-air pursuits. During the recent campaign the City Imperial Volunteers marched under arduous circumstances of war a distance of thirteen and a half miles a day for over four months, and at one time during thirteen marching days averaged seventeen and a quarter miles a day. The *Lancet* editorial writer believes that the reason of this lies in the progress that has lately been made in the conditions of urban life generally. He finds that in London as much as in any other city of Europe athletic pursuits of various sorts are considered a necessary adjunct to healthy living; the bicycle, golf, football, gymnasiums, swimming baths, and various organizations provide most popular forms of athletics. Cricket, and lawn tennis are nearly as valuable. Fifty years ago about the only relaxations of the London city clerk were boxing and billiards, and these were often sought in the annexes of public houses and in dubious company.

This severe test of the strength and endurance of a large company of city-bred men does seem to indicate that opinions as to the improvement in the physical condition of the present dwellers in cities has not been overestimated, though no doubt the men forming the City Imperial Volunteers were a picked body of men. While this improvement in the sanitary conditions is most encouraging, we should not permit ourselves to be blind to the need for still further advances. In all of our large cities there are overcrowded slums. The tenement-house evil is still very great; in many cities the water-supply is most miserable; in all but a few of the most progressive cities the drainage is equally bad and, in many, there are many other matters of great importance, such as the milk-supply, which demand the attention of sanitarians. No doubt the improvement in American cities has been as great during the past fifty years as in London, and this rests in large part upon the efforts of the medical profession and on organized effort to secure future needed progress.

Tenement-house Legislation.—The recent publication of a report of nearly 200 pages upon "Tenement-house Legislation in New York, 1852-1900," prepared for the Tenement-house Commission of 1900 by its Secretary, Mr. Lawrence Veiller, is an admirable record and illustrates the varying phases through which this important problem has passed. It is the first account of the kind that has ever been published, and it must prove of great interest and value to architects, builders, lawyers, and sociologists. It appears that laws relating to the construction of buildings in New York City were first enacted in 1647, but it was not until 1852 that special consideration was given to houses occupied by more than three families, while the term "tenement-house" did not appear in the statutes earlier than 1862, and it was not until 1867 that the first special law with reference to tenement-houses was passed.

In this report the different statutes are classified with reference to the purpose of their enactment as Fire provisions, Light-provisions and Ventilation-provisions, Sanitary Provisions and Health-provisions, and General Provisions Relating to the Administration of the Laws. Among the precautions against fire are considered such subjects as fire-escapes, the construction of public halls and stairways, of wall-partitions, of elevator-shafts, of dumb-waiter shafts, of light-shafts, of vent-shafts, etc. In providing for adequate light and ventilation the amount of space to be left between front and rear tenements, at the rear of tenement-houses, the percentage of the lot that may be occupied by new tenements, the size of light shafts and air-shafts, the ventilation and the size of rooms and halls, etc., are taken into consideration. An account is given of the changes that have taken place at different times with regard to the various phases of the subject, with the exact language from the actual enactments, and including the present law. A list of all of the laws that have been enacted in the State of New York with reference to buildings in general and tenement-houses in particular from 1849 to the present time is given at the close of the report.

It is interesting to note that many good laws were enacted 20 or 30 years ago that were in some respects more rigid than those of the present day. Thus, the law of 1867 required that in all tenement-houses to be occupied by 4 families or more the stairs and halls should be entirely fireproof (stone or iron) and the floor-beams of the halls of iron, with brick arches; while the present law does not require stairs to be absolutely fireproof except in buildings over 5 stories high and arranged for 4 families on every floor; under other conditions the stairs and halls must be constructed of slow-burning material, and for tenement-houses less than 3 stories high no special provision is made.

Again, the law of 1867 required that in all tenement-

houses to be occupied by 4 families or more, the hall-partitions from the foundation to the roof should be made of brick, not less than 12 inches in thickness, and that the floor-beams of such halls should be of iron, with brick arches; while the present law limits these requirements to the stairways and the partitions enclosing them, and does not apply to the whole public hallway. So, too, the law of 1871, with reference to fire-proof construction of the first story was much more rigid than the present law, the former requiring that in all tenements over 3 stories in height, occupied by as many as 6 families above the first story, the first floor should be entirely fireproof, while at present this requirement is made only of buildings 5 stories in height and higher. As early as 1867 all wood-bins and coal-bins in the cellars of tenement-houses were required by law to be constructed of fire-proof material, but this law was repealed in 1871, and a great many serious tenement-house fires have since resulted in consequence. The law of 1887 prohibited the use of any wooden building as a tenement-house; that is, by more than 2 families, while the present law permits the occupancy of such buildings by as many as 6 families. The report contains much additional valuable information, and will repay careful study by those interested in the matters with which it deals.

Medical Sermonets, No. 23. Professional Cards and Signs.—By the same mail we receive three letters concerning three phases of "professional advertising"—all relating to methods of making known the specialty. The first asks:—

"If a man should advertise in a medical journal that he did clinical microscopy for other doctors at certain rates would it be ethical and would it be in good standing?"

We think it highly desirable, as well as absolutely inevitable, that the best professional work should be done by those exceptionally able and fitted to do it. The experts and the specialists under proper professional rules and ideals are pushing forward professional progress not only theoretically but practically. That they should be paid for their special work goes without saying. In answer to the foregoing question the answer, Yes, would seem most clear.

The second inquirer asks if the words "surgery and consultations" or "practice limited to surgery," placed upon his professional cards and the circulation of these cards strictly limited to the profession, would be "professional."

The third correspondent writes as follows:—

"Many complaints are made that physicians who limit their practice do not confine themselves to their specialty. It is unfair to the general practitioner that the specialist should attempt to treat a disease that does not pertain to his specialty. For instance, a physician a few months ago sent a patient, who had recently lost the sight of one eye, to an oculist who made a diagnosis of syphilis. The patient was then sent to his family physician under whose treatment he completely recovered. As the reputable specialist depends very much on the support of the general practitioner for patients, it is his duty to place himself in such a position that every patient who enters his office will know that he makes a specialty of one thing and does not pretend to treat anything else. He can do this only by having his specialty on his sign and on his office door. For six years I have had my specialty on my office door and not more than once a year do I have a patient come to my office for anything that does not pertain to my branch of medicine.

"If every specialist would do this there would be little opportunity for him to do anything but special work. The general practitioner, also, would feel more like sending his patients where they may see that the physician to whom they are sent limits his practice, and is

not simply a physician who knows more about everything than the family physician."

At first sight these arguments seem logical. Upon closer examination we think they are more than neutralized by others. Even in the heart of great cities it is so exceptional for patients to err, e.g., in seeking for the services of an oculist when they wish an obstetrician, that the emphasis of the need for specialist signs or notices may easily be exaggerated. So far as concerns one's professional brethren, even in cities, they soon learn the specialty and desires of each as to practice. The doubt as to whether one honorably sticks to his specialty is, or may be, easily cleared up. One of our oldest and most honorable national medical societies makes it an invariable rule not to accept as a member any applicant who, on sign or card, makes known the fact that he is a specialist. We think the rule a wise one. All such methods of advertising are outgrowths of the commercialism of medicine, of looking upon the cure of disease as a business, and of thinking of the patient's ability to pay before determining as to the treatment. Medicine, it cannot be too often urged, is neither business nor knowledge nor success; nor is it all three combined. All three are more or less necessary but subordinate parts or bases of the professional life, but skill, the cure of disease, *the art of medicine*, is something far different and higher. Can we not keep the old, simple, kindly, personal relations with our patients? and also with our professional brethren? It surely is not necessary to mechanize our calling and harden it after the manner of the world in military and commercial life. Let us continue on our older genial and human way of quietness and modesty, wherein we need not placard our peculiar abilities. Whatever tends toward, or is in danger of being construed as advertising, does us no good in the long run, and is destructive of the true ideal of the physician. However great the skill or the knowledge, it is our most honorable pride that these qualities should but light us on the way of love and beneficence.

Exercise in the Treatment of Tuberculosis.—Parker Murphy (*Albany Medical Annals*, November, 1900) insists that a proper system of respiratory gymnastics is very essential in the treatment of tuberculosis. This is especially necessary for persons leading a sedentary life and who for that reason are denied the invigorating fresh air and the deep, full respiration induced by vigorous exercise. He says the splendid results of high altitude in the treatment of tuberculosis have not been due to any curative constituent of the atmosphere or any peculiarity of temperature, but entirely to decreased barometric pressure upon the external surface, compelling a greater expansion of the chest, opening up a larger surface for the interchange of gases and consequently a greater oxygenation of the blood. It is self-evident then, that the forced distention of the lungs and bronchi in those who live in high altitudes, alone confers immunity against the disease. The exercises available to produce better respiration are very numerous and varied, but the underlying principle is simply to bring into more vigorous play the muscles which expand the thorax and at the same time excite deep, full and free breathing; to bring the vital force of the lung to its maximum. All exercises of the thoracic muscles for the purpose of producing an increase in that cavity must at the same time be coincident with deep breathing. The amplitude of the respiratory movements must be increased; the lungs must push out from within, as well as the thoracic muscles pull from without. We should labor incessantly in the advocacy of a more general use of physical training so that the large lung surface necessary to our physically active and vigorous, savage ancestors may not become a redundancy when it is transmitted to our higher civilization, in which everything tends to produce a condition of physical inertia. [A.B.C.]

Reviews.

Tuberculosis: Its Nature, Prevention and Treatment. With Special Reference to the Open-air Treatment of Phthisis. By ALFRED HILLIER, B.A., M.D., C.M. With 31 illustrations and 3 colored plates. 8vo, pp. 243. London, Paris, New York, and Melbourne: Cassell & Company, Limited, 1900.

Tuberculosis has in all times been made the object of careful study, and efforts in its prevention and cure have been unceasing. Only since the discovery of its cause and of the unity of the various morbid processes to which it gives rise, however, has it been possible to treat the disease with the intelligence necessary to insure a fair measure of success. The last decade of the nineteenth century has witnessed great activity in the field of preventive medicine, and, all things considered, it may be said that with regard to no disease has greater progress been made in this direction than with regard to tuberculosis. Not alone has the tubercle-bacillus been made the point of attack, but also effort has been directed to fortifying the individual resistance, and the near future promises to show continued increase in the reduction in morbidity and mortality already in progress. The little manual before us discusses the various phases of tuberculosis in 8 chapters, as follows: I. Nature of Tuberculosis. II. Different Forms of Tuberculosis. III. Transmission from Man to Man. IV. Transmission from Animals to Man. V. Prevention in Everyday Life. VI. Prevention by Legislation and Public Action. VII. Treatment of Tuberculosis. VIII. National Movements Against Tuberculosis. The text is well written, the illustrations are appropriate, and the result is a book that should prove serviceable especially to the medical practitioner.

The Care of the Consumptive. A Consideration of the Scientific Use of Natural Therapeutic Agencies in the Prevention and Care of Consumption, Together With a Chapter on Colorado as a Resort for Invalids. By CHARLES FOX GARDINER, M.D. 8vo, pp., vii, 182. New York and London: G. P. Putnam's Sons, 1900.

The author of this little volume has undertaken the big and by no means easy task of laying down for popular reading "the rules that should govern the consumptive in the use of fresh air, sunlight, food, rest, and, exercise, so that these natural therapeutic agencies can be applied to the best advantage," and he has succeeded fairly well. The subject is considered in 11 chapters: I. The Nature of the Disease; II. Infection; III. House Hygiene; IV. Outdoor Life; V. Food; VI. Clothing; VII. Exercise; VIII. An Invalid's Body; IX. Psychology of the Sickroom and Treatment of Emergencies; X. Care of the Consumptive's Children; XI. Colorado. The present is essentially an era of education in preventive medicine, and to this end books like that under consideration make contribution.

Early Diagnosis of Tuberculosis.—Schaeffer (*Maryland Medical Journal*, November, 1900) insists that this is of the utmost importance; and the physician should be able to diagnose it without bacteriologic tests. Percussion and palpation will elicit a change in the affected apex; a crackling, respiratory sound is heard, and if a subfebrile temperature at the same time exists, the diagnosis is practically made. In doubtful cases the author has used injections of tuberculin. If to 1 mg. of the original fluid there is a response of 38.5° C. and over, to $\frac{2}{3}$ mg. of 39° C., he considers the result practically conclusive. Creasote does not affect the tuberculous process, but is of value as a stomachic. Ergot and styptics are valueless in the treatment of pulmonary hemorrhage. Psychical quieting of the patient, rest in bed, and the relief of cough are to be accomplished. For this purpose the sucking of ice, ice-bladders over the lungs, and morphin or codein are the indicated remedies. [A.B.C.]

Correspondence.

A PATHOGNOMONIC SYMPTOM OF TUBERCULOUS PERITONITIS.

By M. OSIAS, B.Sc., M.D.,
of New York.

To the Editor of THE PHILADELPHIA MEDICAL JOURNAL:—

I DESIRE to call attention to a characteristic sign, which I observed in all the eight cases of tuberculous peritonitis I have treated, and which always confirmed the other symptoms of tuberculous peritonitis.

In palpation of the abdomen in a case of tuberculous peritonitis, when pressing either gently or profoundly on it, the patient will complain of little or no pain at all, while the moment the hand is taken off by the examiner the patient complains of great pain in that part of the abdomen and usually manifests the painful sensation by a cry. I elicited this physical sign from all the patients suffering from tuberculous peritonitis, and therefore think this palpatorial sign is an important factor in the difficult diagnosis of primary tuberculous peritonitis.

Problems Pertaining to Tuberculosis.—Holmes (*Denver Medical Times*, November, 1900) says that those having tuberculosis who make an early change to a congenial climate are unquestionably benefited, but that those who live in such resorts are exposed to great danger of infection. This is reacting on public sentiment in these localities and the tuberculous are not welcomed. He does not believe in establishing the quarantine, but that a mutual, intelligent understanding and spirit of cooperation should be secured between the States possessing climatic advantages and those States without them. Sanatoriums should be established in these favored localities, not only for the better care of the afflicted, but also to provide a retreat for those sadly in need of climatic treatment. [A.B.C.]

Tuberculous Lesions.—Edmund Owen (*The Canadian Journal of Medicine and Surgery*, October, 1900) says 3 important facts in connection with tuberculosis should be remembered, viz., the disease is communicable, it is preventable, and it is curable. With reference to the latter he draws the following conclusions: 1. Chronic inflammation of a joint in a child or young person is always tuberculous—except in those very rare cases in which it is due to hereditary syphilis or osteoarthritis. 2. Tuberculous inflammation may completely destroy a joint, and then leave it solidly and soundly synostosed, without the surrounding tissues or the skin having been implicated, as in *caries sicca*. 3. If tuberculous granulation-tissue breaks down into a fluid, that fluid is not pus, and the collection is not, properly speaking, an abscess—unless, by bad fortune or by worse surgery, it has become infected by septic microorganisms. 4. The fluid collection is not to be treated as an abscess—by incision and drainage, that is—but is to be opened and emptied, and scraped and cleansed of its unhealthy lining of granulation-tissue. Then the wound in the skin is to be completely closed by sutures; firm pressure is to be evenly applied, and the part is to be kept absolutely at rest—by a splint if practicable. 5. The author has failed to discover that iodoform is of any peculiar value in the treatment of tuberculous lesions. At any rate he has long since discarded it, and has not noticed any falling off in the results in consequence. He says there may be a small class of cases of angular deformity of the spine which should be treated by forcible rectification, but the application of such a procedure must be very limited. In the treatment of vertebral caries he insists upon securing absolute rest by putting the child flat on his back in a pillowless bed. There are all sorts of schemes, corsets, apparatus and braces for treating spinal caries without keeping the child flat. But they are all wrong in theory and in practice; and if every case of spinal disease could from the beginning be treated by continuous rest in the horizontal position, there should be no more of those unsightly humps to invite speculative interference. [A.B.C.]

Society Report.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Meeting Held November 14, 1900, to Consider Registration of Tuberculosis.

[Specially reported for THE PHILADELPHIA MEDICAL JOURNAL.]

AT THE meeting of the Philadelphia County Medical Society, November 14, DR. HERMAN M. BIGGS, of the New York Department of Health, read a paper entitled, **Registration of Tuberculosis** (see Original Article Department), which was illustrated by stereopticon views.

DR. A. C. ABBOTT, who opened the discussion, said that he believed that if the workings of this system of registration and the object aimed at were definitely understood there would be no necessity for discussion; that the **opposition to registration** in connection with tuberculosis is due largely to a misunderstanding of the subject. It is not the intention of the authorities to place tubercular subjects in the same registration with those suffering from acute transmissible disease, but the object is to get precise data as to where cases of tuberculosis are located, in order that the authorities might be able to cope with the infected localities. The Board of Health of New York in dealing with the subject discriminates between those intelligent persons who know what measures to adopt in order to prevent the spread of disease and the ignorant, careless persons who have a complete disregard for the health of the community and therefore must be placed within the pale of authority.

Dr. Abbott believed that the great objection which had been made to the reporting of cases of tuberculosis, that the individual would be a social outcast, was "perfect rubbish." "There is no earthly reason why that individual should not be reported to the authorities as a tubercular subject. His physician should report him, but the individual should not know it; and if this individual occupies a social position that will guarantee intelligent observation of the directions given him by his physicians, there is no earthly reason why the authorities should fear in the least, but unfortunately these physicians cover a very small community. In a very large proportion of the community in which tuberculosis exists and in which it forms a menace to our people who cannot or will not, or perhaps both, follow the directions of the physician, my belief is, in these cases, the Board of Health should be authorized to look after them, to disinfect the premises. And how are they to know where these homes are if they are not located? I cannot see any objection to registration of tuberculosis." The doctor, in closing, said that, for a large part, these tuberculous patients should be wards of the State, that there should be organized sanitariums in which these individuals should be comfortably quartered and where proper employment could be controlled by expert sanitarians.

DR. JAMES WILSON said that he had been deterred from coming to positive conclusions in regard to the matter, not so much by the specters that have been called up to frighten those who advocate the system of registration of cases of pulmonary consumption, as by the doubts in the matter, doubts which are fully realized by those who are most interested in the subject. He had always thought that in instituting a radical public measure, such as the one under discussion, those who seek to establish it should ask themselves definitely a question: **What good objects are to be obtained by the measure?** There are two main objects besides the collateral basis. The first relates to statistics, in a broad sense the determination of the proportion of individuals in any community who are infected, the age at which the infection takes place, progress, mortality, and matters of that kind. The second relates to preventive medicine, and the two are, of course, largely interdependent.

Dr. Wilson believed that, regarding the first proposition, the medical profession would entirely favor its accomplishment by any such regulations, but that the mental attitude of the profession was hostile to any such measure that would scarcely be enforced, except in limited areas, and limited enforcement without cooperation of the entire profession would make such additions to statistics absolutely worthless and largely misleading. It is only by the educa-

tion of the profession that the greatest value in this measure can be realized, and the education of the profession means the education of the people. He was of the opinion that the thought of social ostracism resulting from the isolation of a dear friend or member of the family suffering from this dread malady had created a panic in the minds of certain physicians who were thus influenced to oppose the proposed measures.

DR. MEIGS was opposed to the features proposed in the essayist's paper for registration. He said there were two things that made it **undesirable that there should be a forcible registration of tuberculosis.** "The first is, I think—there will happen to us in this city, and I believe it happens in New York to a greater extent than Dr. Biggs believes or would be willing to accept. I was very much struck with the different attitudes of those engaged in Board of Health work and those engaged in the laboratory work, in the attitude of the practitioner in regard to the thing—the difference of opinion the two sets of men have in regard to the results. In the first place, I do not think it can be successfully accomplished, and I do not think there will be any adequate return of good." He was of the opinion that Dr. Biggs is deceived in the belief that such a very large number of physicians report tuberculosis. "This experiment of the registration of tuberculosis was undertaken in Naples one hundred years ago and the laws which were in force in that city long since have fallen into desuetude or were repealed. Whether, in the second place, there is any adequate gain to the health of the community is another question. I do not believe there is any adequate gain for the hardship put on the individual. I cannot drop the question without saying that I do not believe that consumption is infectious from the way that Dr. Biggs and all bacteriologists say. I do not believe that the great bulk of the medical profession believe in the communicability of tuberculosis, by those who are looked upon as authorities in this matter."

Dr. Meigs then amused his auditors by reading excerpts from Continental authorities, including the opinions of Sir Andrew Clarke. He stated that Mr. Duncan Turner termed the first edition of his book, "Is Consumption Contagious?" and in the second edition he entitles it, "Consumption Not Contagious." The doctor believed that there were a great many persons who were said to have tuberculosis when they were not suffering from that disease. In closing, Dr. Meigs said: "I am opposed to it. I do not think it can be practically carried out. I do not believe it is practically carried out in New York, though I have no direct knowledge in this matter, except from my general knowledge. There is no adequate gain if it is carried out, and I do not believe it is contagious in any form or that it does any harm in that way."

DR. ANDERS complimented Dr. Biggs upon his temperate statement of facts and arguments in favor of placing this disease on the list of affections returnable to the Board of Health. The first question in his mind that should be settled was this: **"Is tuberculosis a preventable disease?"** He cited that there was a decrease in the death rate of tuberculosis in Italy under the Neapolitan law; this law included among other measures compulsory notification and isolation. In his opinion tuberculosis is a preventable disease. Then, another query presents itself: **"Is compulsory notification essential to the stamping out of this prevalent affection? Is it an essential part of our armamentarium, in our efforts to minimize the spread of the mortality rate of this disease?"** "The foci in this disease must be recognized, and recognized by some centralized authority with sufficient intelligence and power to act; otherwise the sources of infection will not be successfully removed. Physicians can advise disinfection, but unless they are entitled to a fee, they cannot be expected to see that it is properly carried out. I also believe it is entirely practicable to institute compulsory notification. In the first place, as has been said, it does not imply placarding houses, strict isolation, as in the case of acute infectious fevers, and I was very glad to see the point brought out that it does not even necessitate publicity of any sort. On the other hand, compulsory notification would insure closer attention to important details, with regard to disinfection of sputum, of clothing, of furnishings, and, more important of all, of rooms vacated either by death or removal from place to place, and this is of especial importance among the poorer classes whom the Good Book says 'we shall always have with us.'

and who will probably never become sufficiently enlightened to protect their fellow men from the dangers of infection. This is perhaps the greatest reason for the institution of a measure of this sort. I am, therefore, for the reasons I have stated and for the reasons that Dr. Biggs and others have given, in favor of compulsory notification, provided that the simplest measures only are employed, particularly at the outset, and in order that this new law, if it should go into effect, would not lead to its rejection on humanitarian grounds."

DR LAWRENCE F. FLICK was in entire accord with what Dr. Biggs had stated in his paper. "If it is a communicable and preventable disease," said Dr. Flick, "then I think what Dr. Biggs has shown us tonight and has said to us forces us to the radical conclusion that **registration and forcible notification are necessary.** He believed that no one could convince himself by reading, but rather by practical experience amongst the poor. He cited the case of a doctor who had previously opposed registration until, by close association with poor consumptives, he was converted to the belief that registration was essential. Whilst tuberculosis is not as intensely contagious as smallpox for the same period of time, given the length of time which the disease lasts, the habitation of the consumptive does become as intensely capable of communicating the disease as does the habitation of the smallpox patient. Therefore, there is just as much reason for the disinfection and the proper surveillance of the habitation of the consumptive as there is for the surveillance of the habitation of the smallpox patient." The doctor cited the fact that within the last 6 years, in connection with the work for the Free Hospital for Poor Consumptives, there were between six and seven hundred people that applied for admission. They lived in the most unsanitary habitations, the conditions of which making it absolutely certain that they would become infected, and that they would acquire the power of communicating the disease to the next inhabitant. The doctor thought that the proper disinfection and sterilization of the rooms and houses were of a nature too expensive for the occupants or owners of the houses voluntarily to carry out, and that the only way that these measures could become efficacious would be through the board of health. "We have in the city of Philadelphia, probably at all times, from four to five thousand tuberculous subjects. Probably at least four thousand of these are among the poor and working classes. Every physician who has had experience in that class knows that with all the instruction that the physician can give it will never induce the patient to make himself innocuous to his surroundings and those about him, or will induce him to prevent the contamination of the house in which he dwells, the contamination of the clothing and everything about his home center, and unless you know where that home center is and have sufficient means of getting at it and cleaning it out sufficiently by some one who has no financial interest in it, we cannot hope to eliminate or stamp out that distribution of disease." The doctor referred to the success attending the use of preventive measures in England and the reduction of the disease in London of 50% in 40 years. In his opinion there is no rational explanation of the reduction, except through the fact of removal of the consumptive poor from the home center. He refuted Dr. Meigs' assertion that the preventive measures practised in Italy a hundred years ago had no practical results. They did have practical results, that through isolation, etc., tuberculosis in that country, under the Neapolitan laws, for a period of 40 or 50 years was reduced to probably as high as 87%. He claimed that the same laws had never been repeated and were probably on the statute books of Italy and allowed to become a dead letter because of the active opposition which arose from the medical profession.

DR. ORT stated that Dr. Biggs' paper confirmed the conclusions that he had drawn some years ago, having spent the greater part of his medical life in general practice, and chiefly among the poor. He pointed out the **necessity for thorough sterilization of houses** previously occupied by consumptives. Of one house in particular he had warned 3 members of a certain family who successively occupied it, and in the course of 6 years, each one lost a member by tuberculosis. "I believe in the registration of tuberculosis, and not alone in the registration, but in the isolation of the cases as far as it can be humanely carried out." He pointed out, however, a possible difficulty that would have to be

overcome by the requirements of registration, namely, that of estrangement between physician and patient when the former informed the latter that such measures would be put in force. "I believe furthermore in tuberculosis being preventable, and also in its being communicable. I, however, believed that for years, and I drew that conclusion from bedside work some time before Koch discovered the tubercle-bacillus and also established the law that the germ must be discovered in the patient and must be reproduced in a culture medium, must be injected into an animal and then the same germ discovered in a disinfected animal. I believe that tuberculosis is an indoor disease, and the sooner we learn to live out of doors, the more quickly probably we will reduce the mortality.

"There are a great many tuberculous persons who are intelligent and understand thoroughly the necessity for care in the sputum, the possibility of communicating the disease to the family or those who are immediately around them, who exercise the requisite amount of care to prevent this transmission of disease. Those individuals require no consideration through sanitary authorities. They are to be grouped with those classes or groups of the insane who are not in any way at all a menace to those around them or to the general public. On the other hand, in the lower classes, the poor, the necessity for care is greater than in any other class. The conditions are entirely different; it is absolutely necessary that these individuals should be educated. The education of the family may be just as important as the education of the patient, and it may be more so." The doctor stated that some 8 or 10 years ago the Government appointed a commission to look into the districts of the poorer classes—the slum districts—of the cities of the United States. Dr. Coplin accompanied the representative appointed to Philadelphia on his rounds for the collection of cultures. In some cases the knowledge of the existence of tuberculous patients was secured from policemen on the beat who knew the houses occupied by individuals suffering from this disease. There was one house which had a continuous history of tuberculosis for over a quarter of a century, and there was a house on Master street in which there had been tuberculosis for nearly 23 years. "These foci are officially unknown. There is no official way by which sanitary authorities are apprised of such conditions in the absence of registration. It seems to me it appeals not only to the patient and family, but to the community."

DR J. SOLIS COHEN spoke as follows: "I gather from Dr. Biggs' very excellent paper that his 4 years' experience in New York has done a great deal of good and has done no harm. As a matter of sentiment, the **idea of registration is objectionable to me personally**, as it is to a great many others. When we have considered the greatest good to the greatest number, I must confess, with him, that the interests of the individual and family would be made subservient to those of the community." (Applause.)

DR. MATTHEW WOODS said that when this question was brought up 3 or 4 years ago he was one of those who opposed registration. Since that time he had given attention to the subject and read most of the literature published in regard to it and that he still remained opposed to registration. The doctor said that in the Pathological Department of the College of Physicians in Dublin he saw a very interesting series of tuberculous lungs of domestic and wild animals, "A great many of these animals were not in the habit of spitting at all. You know that *man* has been defined by one of the earlier philosophers as 'the animal that spits.' (Laughter.) Some one has said, 'the animal that uses a pocket handkerchief.'" He said that in that series of animals to which he referred there were lungs of fishes that had died in a London aquarium of tuberculosis, and domestic fowls, and, you know, that consumption is the disease of caged animals. Monkeys, tigers, lions, elephants, all, or nearly all, died of consumption. "And I think that the arguments, therefore, that have been used by the gentlemen in favor of registration would apply more definitely to locations than to people. I still feel that not the people, but that the locations should be registered. The foci should be known to the authorities and these places should be stamped out by proper sanitation. Indeed, the Board of Health in Philadelphia neglects so many of its duties as it is, that I feel, as a humanitarian, as a human person, we should not load them with additional duties." He related a case of a dying consumptive to whom

he had been called somewhere in the slum districts of the city. He found the room a mass of filth, the floors slippery and the walls encrusted with dirt. In the back yards the filth was piled up right to the fences, so that he was of the opinion that the Board of Health should give more attention to the location of the houses and streets and let the poor victims of consumption alone. He was of the opinion that the registration of such diseases as scarlet fever and diphtheria did far more harm than good and that, therefore, harm can be done by the registration of acute diseases. "I think we should pause and hesitate a long time before putting these comparatively, only very comparatively communicable diseases from person to person, on the list of diseases that should be registered."

DR. SIMON FLENNER was the next discussor and spoke as follows: "I had no intention of adding anything to the very able presentation of the subject by Professor Biggs and the very full discussion on the subject by the members of the County Medical Society, and I dare say that I should not had it not been for Dr. Woods. I take great pleasure really now in taking a cue that he suggested, that is, the **relation of the tuberculosis of wild animals**, especially after they are caged and with reference to the question of communicability of tuberculosis in man. Of course, before one undertakes to discuss this subject he should have clearly in mind what tuberculosis is. Without that it is impossible to arrive at any proper solution. Now, there are conditions which simulate tuberculosis which are not tuberculosis unless we insist that a tubercle or nodule is always tuberculosis. A nodule on the bone is not tuberculosis; every nodular disease of animals is not necessarily tuberculosis, even if it appears so. Fishes are not subject to tuberculosis, but are subject to nodular diseases and parasites and also sheep are subject to nodular diseases and parasites which are not tuberculosis, not from the ordinary pathologic and medical standpoints. Many of the wild caged animals are subject to tuberculosis, but they are not subject to it until they come into relation with man's products. As to the animals being subject to the disease, I think he simply proves the communicability of the disease when he shows that animals in the state of nature have not that disease until they are brought into relation with man, when that develops the disease. They are arguments of modern civilization. If animals are fed on tubercular food, and we do not take particular care in feeding our wild animals in cages, they will have tuberculosis just as man will. It seems to me that Dr. Woods has provided the missing link in the argument which Dr. Biggs brought forward, namely, the great danger of the communicability of tuberculosis, not alone from human beings to human beings, but from animals to human beings and from one animal to another. In regard to registration of the foci of tuberculosis, how are we going to get at the sites? The sites do not suffer, but the individuals who occupy them, and if it is important to register those sites, to be done in a mild manner, as suggested by the essayist this evening, which does not expose human beings to isolation and, therefore, there cannot be any objection, what can be more important than the determination of those sites by registration of these cases, in order that the matter may be properly dealt with by the authorities?"

DR. HINSDALE stated that he thought the time had come when the **Society should take some positive action** in the matter. He said that the Board of Health of Philadelphia was only waiting for some measures to be received by them and that their attitude was friendly.

DR. STENGEL said that there was no question about the position of the medical profession regarding tuberculosis, that it is a **communicable disease** beyond all question of doubt, not only communicable but mildly contagious—a disease which is mainly communicated through the expectoration and other secretions or excretions from the lungs. He said the question is whether registration will do any good. The only good that registration can do is to apprise public officials of the existence of tuberculosis in certain cases or certain places and empower those officials to follow that case of tuberculosis and instruct so as not to hurt the feelings and not interfere with the orderly life of the individual in the prevention or spread of the disease, or else that the physician in charge of that case shall be instructed and required by that Board of Health to so instruct the patient. "If the law is so administered in a kindly way, and as I have

always found the law administered by the Board of Health in the city in cases of other contagious diseases, there is no reason why any physician should feel aggrieved at any action of a public official. Registration can do great good and it will not injure the physician materially in his daily avocation and, therefore, it seems to me that it is high time in this city we should rescind our action formerly and appeal to the public officials again to bring up this matter and frame a definite law."

DR. ANGENY stated that the Board of Health does provide for Dr. Woods' foci disease, that someone is sent to the house after death and the **house is fumigated**. He believed that there is need for the proper instruction of the people to prevent them from infecting others.

DR. EGBERT was of the opinion that by the adoption of these measures each patient and his family are no longer a focus of infection but of education, and that is really the one way through which we are going to gain ground. "As has been remarked tonight, there has been a decrease in the death-rate from tuberculosis throughout the country, and I think Dr. Flick will bear me out in the statement that we have a less death-rate from tuberculosis in this city today than we did 15 years ago. If the laity were educated in this city there would be no tuberculosis in a very short time. There is one other indication besides this education by means of infection, that is, the education of hope." The doctor believed that hope will help many a patient to resist disease.

The following resolution was proposed by Dr. GUY HINSDALE and read by the secretary:

Resolved, That the Society recommends to the Bureau of Health of Philadelphia the compulsory registration of tuberculosis in the class of transmissible diseases and that measures for its prevention be adopted."

Upon motion the resolution was adopted.

A motion to appoint a committee of 5 to urge the Board of Health to introduce the resolution was lost by one negative vote.

DR. BIGGS, in closing the discussion, said: "In regard to calling tuberculosis contagious or communicable, it has always seemed to me that there is a definite conception which goes to contagious diseases that does not apply to tuberculosis. There is something about smallpox, scarlet fever, and measles which is entirely different from tuberculosis and the people have that conception just as clearly as we have it. It seems unfortunate to introduce something which is an entirely different thing into that class. It has always been classed a communicable and not a contagious disease. In regard to reporting cases, about 10,000 are reported. We have about 9,000 deaths. We have estimated from 16,000 to 18,000 cases occurring in children. Of course, this is not what we would like. But 10,000 cases with 9,000 deaths gives us about 20,000 cases a year to inspect and take care of. With our present force, it is all we can attend to."

The doctor related several instances of persons contracting tuberculosis, showing conclusively its communicability, and in one case where 13 nurses had left a certain hospital within a period of 2½ years, all suffering with tuberculosis, yet they were perfectly well when they entered.

Open-air Exercise in Pulmonary Tuberculosis.—Knopf (*Pulmonary Tuberculosis*, 1899) writes as follows concerning exercise for pulmonary invalids: "One should commence with a walk of a few minutes until a walk of an hour or an hour and a half can be taken without producing fatigue. Whenever it is practicable these excursions should begin uphill, so that the return is easy. After the promenade the patient's temperature should be taken. If it exceeds the normal it is an indication that the patient has overtaxed his powers. Whether complete rest or simply shorter walks are then indicated will be decided by the variation in temperature of the temperature before and after exercise. When the temperature of the patient only rises slightly in the evening (99° to 99½° F.), short walks in the morning, while in apyretic state, may be permitted. A lasting temperature of 100° F. or over is an absolute contraindication to exercise. Tachycardia should also be considered as such. If there is, however, a chronic tachycardiac condition, absolute rest might not be the best policy. But these patients, more than any others, should be warned against the slightest overexertion. Breathing exercises and walks may be combined." [A.A.S.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Calendar of Meetings of Philadelphia Medical Societies for the week ended December 8, 1900:

Monday, December 3—Academy of Surgery.
Wednesday, December 5—College of Physicians.
Thursday, December 6—Obstetrical Society.

Dr. James Hendrie Lloyd has resigned his position as neurologist to the Philadelphia Hospital.

The Epidemic at Cementon.—The cause of the epidemic at Cementon, which afflicted 160 families and claimed several victims, has been traced to its source. A dead horse was found recently in the reservoir which supplies the town with drinking water. It had evidently been there for some time.

Disposal of Sewer Gas.—Tests are now being made with the object of ridding Philadelphia of sewer gas. The best means for its disposal is claimed to be combustion through a high temperature, and a patent sewer gas extracting and destroying lamp that has proved successful in Europe is being used in the experiments.

Disinfecting Barges have left Philadelphia, towed by the steamer *Orion* for Cuba, one to be put in service at Matanzas, and the other at Cienfuegos. Another barge is now being equipped for quarantine-work at the Kensington yard, destined for a port in Porto Rico. The Kensington works are now constructing disinfecting machinery for a fumigating barge, which is being built at Mobile, to be used at Ship Island, Miss.

Physicians Victims of Impostors.—About a year ago a man representing himself as Dr. A. C. Dolrenz called upon the physicians of Atlantic City to solicit a small loan to establish himself as a druggist at Egg Harbor City. He collected about \$50. Recently a young man representing himself as a son of Dr. A. C. Dolrenz visited the physicians with a letter of introduction stating that his father had met with financial difficulties and again asked for aid. An investigation proved that such a person is unknown in Egg Harbor City. The police are now looking for the impostor.

Vital statistics of Philadelphia for the week ended November 24, 1900:

Total mortality	CASES.	DEATHS.
Inflammation of appendix 1, brain 8, bladder 1, bronchi 5, kidneys 15, larynx 1, heart 1, lungs 64, peritoneum 5, pleura 4, spine 1, stomach and bowels 17		123
Lungs—tuberculosis of 41, edema of 2		43
Heart—diseases of 31, fatty degeneration of 4, neuralgia of 3		38
Marasmus 14, inanition 14, debility 5		33
Apoplexy 17, paralysis 13		30
Uremia 14, diabetes 1, Bright's disease 6		21
Casualties		16
Diphtheria	112	15
Convulsions		13
Carcinoma of breast 1, leg 1, larynx 1, liver 2, neck 1, rectum 1, stomach 2, tongue 2, uterus 2		13
Old age		10
Croup 1, membranous 7		8
Liver—cirrhosis of 5, sclerosis of 2		7
Colic		6
Brain—congestion of 3, softening of 3		5
Suicide—carbolic acid 2, illuminating gas 2, shooting 1		5
Septicemia		5
Burns and scalds		5
Typhoid fever	43	5
Gangrene		3
Scarlet fever	57	1
Aneurysm of aorta 1, alcoholism 1, asthma 2, cerebrospinal meningitis 2, cyanosis 1, drowned 1, dropsy 1, epilepsy 1, erysipelas 2, hernia 1, indigestion 1, jaundice 1, obstruction of bowels 1, opium poisoning 1, rheumatism 1, shock—surgical 1, electric 1, stricture of the esophagus 1, syphilis 1, tetanus 1, ulceration of stomach 1		

Philadelphia Hospital.—By order of Dr. Shoemaker, the ambulances of this hospital will, in the future, be sent for cases heretofore taken by patrol-wagons. This, it is stated in the order, will not only save the making of long trips by the patrol-wagons, but is also a more humane and proper way of conveying people to the hospital.

Parasitic Hemoptysis.—Dr. Charles Wardell Stiles, of the Bureau of Animal Industry, Washington, D. C., read a paper on the above subject at the meeting of the Philadelphia Pathological Society, November 22. The parasite causing this disease, the *Paragonimus westermanii*, was described and specimens shown. At present it is found only in animals in this country, 50 to 100 cases in hogs having been investigated. Being an Asiatic disease, the return of U. S. troops makes it an interesting subject at present. The parasite has for its intermediate host a certain genus of snails. The disease is likely to be confounded with pulmonary tuberculosis, the diagnosis being made by finding the eggs of the parasite in the sputum. Treatment is hopeless.

NEW YORK.

Scarlet Fever.—At Williamsville, N. Y., 30 cases of scarlet fever have been reported.

Gouverneur Hospital.—There has been much delay in opening this institution in New York City, the construction of which began 5 years ago. The explanation is that the law requires that all the furniture for the hospital shall be made in the prisons of the State, and they have been slow in fulfilling their contracts.

Damage Suit Disagreement.—A suit which was instituted against Drs. Manges and Rosenberg for \$60,000 damages resulted in a disagreement of the jury, the division being 9 to 3 in favor of the doctors. The suit arose from a simple curettage of the uterus in a case of severe hemorrhage in a woman with large fibroids.

Pasteur Preventive Treatment.—It is announced that the New York Board of Health will furnish the Pasteur preventive treatment free to victims of dogs believed to have rabies. At the Willard Parker Hospital a special laboratory for the purpose will be established. For the past year, 8 or 9 deaths have been reported, a number greatly exceeding the mortality of previous years.

New York Water-Supply.—The chief engineer of the Department of Water-Supply has received official orders to make a complete investigation of the streams, reservoirs, lakes, and ponds in the Croton watershed to see if any improvement in the condition of the water is possible. Its impurity is stated to be due to the drought and growth of vegetation on the sides of the reservoir, and not to any outside contamination.

Purification of the Passaic River.—At a recent meeting of the mayors and engineers of the Passaic Valley municipalities the outlook was discouraging for the plan that the interested cities would unite in the construction of a great trunk sewer from Paterson to Newark Bay. Paterson is opposed to it on account of the cost; East Orange holds that the contract under which it empties its sewage into the Newark sewers makes that city responsible for its final disposal, and the other municipalities have taken no action.

Bequests to Charity.—By the will of Abraham Wo'll the following institutions have been benefited: The Home for Aged and Infirm Hebrews, The Hebrew Benevolent and Orphan Asylum Society, and the Cancer Hospital of New York each received \$5,000. Mount Sinai Hospital, the Montefiore Home for Chronic Invalids, the Society for Preventing Cruelty to Children, the Colored Orphan Asylum, the German Hospital, the Hebrew Infant Asylum and the Children's Aid Society each \$1,000; the Hebrew Technical Institute of New York City, and the Edenkoben Hospital in Germany each \$2,500; the Educational Alliance, of New York, \$3,000, and the United Hebrew Charities, of New York City, \$10,000.

Brooklyn's Water-Supply.—According to the *Ledger* the question of water-supply must be settled by supreme authority soon, as it is growing more urgent every year.

especially in districts dependent upon irrigation. In the Brooklyn case, the water-supply of the city is obtained largely from wells, and these wells drain private property, to its detriment. A decision has been rendered by the State Court of Appeals, that the city must stop using these wells; but this will deprive the community of a large part of its water supply, and what shall be done, not only to prevent the suffering of the people from a water famine, but also to prevent the outbreak of an epidemic, which is always to be anticipated from the conditions thus induced?

NEW ENGLAND.

Infectious Diseases in Boston.—For the week ended November 21, 1900, the following cases of acute infectious diseases were reported to the Board of Health: diphtheria, 169; scarlatina, 29; measles, 24; typhoid fever, 16.

Vincent Memorial Hospital.—By a gift of money from Miss Emma F. Monroe the authorities of this hospital at Boston have been enabled to add the Mary Lowell Stone Memorial Home for Nurses which was opened recently.

Negro Representation on Board of Health.—The colored citizens of Springfield, Mass., have presented to the mayor a petition asking that Dr. A. L. Brown, a colored physician of that city, be appointed to one of the unsalaried positions on the new Board of Health as a capable representative of the colored citizens of that place. Many of the leading white residents signed the petition.

CHICAGO AND WESTERN STATES.

A Chicago College for Nurses has been established with the intention of training women in all the duties of a skilled nurse without requiring 2 years in a hospital or training-school.

The Chicago College of Physicians and Surgeons has received from Dr. William E. Quine, its dean, a gift of \$25,000 to endow its library, and from Dr. D. A. K. Steele, another member of its faculty, a like amount to endow the pathologic laboratory.

The St. Louis Academy of Medical and Surgical Sciences.—At a meeting held November 20, 1900, an address was made by the retiring president, Dr. Ball, on "Early American Medicine." Dr. Prewitt gave a thesis on "Dislocation of head of humerus with fracture of the anatomical neck," and many pathologic specimens were presented by other members.

Wesley Hospital.—Thomas Kent has recently added \$25,000 to the building fund of this hospital in Chicago, which is being built by the Northwestern University as a cooperative institution to the medical college. When complete it will cost about \$250,000, and will accommodate 300 patients. The main building is now being erected, and a wing will be added later.

Marion-Sims-Beaumont College of Medicine.—It is announced that a consolidation of the Marion-Sims College of Medicine and the Beaumont Hospital Medical College will take effect May 1, 1901. The utilization of the teaching force of the 2 institutions and a union of their clinical faculties is contemplated. The Marion-Sims building, with additions, will be used.

Disease Among Chinese.—In a recent report made to the Marine-Hospital Service by the assistant surgeon at Angels Island, Cal., a diseased and filthy condition is depicted among the Chinese aboard the vessels in the Alaskan salmon-canning industry. The condition is probably one of malnutrition with symptoms resembling those of scurvy and beriberi, but not entirely those of either. Their condition is such that they are liable to contract bubonic plague when they return to the slums of San Francisco.

Contagious Diseases in Animals.—The Supervisors' Health and Hospital Committee of San Francisco recommended the passage of an amendment to the ordinance placing the regulation of animals sick with contagious diseases in the hands of the Board of Health. The amendment

allows the owner of such animals to engage a competent veterinary surgeon of his own selection to care for them. It provides also for the quarantine of the infected animal, but the owner is given one month in which to have the proper diagnosis of the contagious disease determined.

St. Louis City Hospital.—An amendment to the ordinance recently passed authorizing the commencement of work on the new City Hospital of St. Louis, has been submitted to the Board of Public Improvements. It was found that the law, as it now stands, makes no provision for the erection of a surgical ward, and without such a building the 2 octagonal wards authorized by the ordinance would be practically worthless. The amendment includes a surgical ward in the list of building to be erected with the money now on hand.

A Temperature of 127° F.—According to the *Medical News*, Robert Bruce, lately returned from service in the Ninth Infantry in the Philippines and China to Chicago, is reported to have this high temperature. Several days ago, Bruce entered the City Hospital and asked for treatment. When the house-physician took his temperature, and found it to be 112° F., and the patient showing no signs of early dissolution, he was astonished. The next day it was found that the clinical thermometer had not sufficient range. Other physicians were summoned, and a government thermometer applied, the mark of 127° F. was registered, and for several days in succession Bruce's temperature has reached this point. It is reported that Bruce's pulse does not go up in proportion to his temperature. An explanation given as to Bruce's condition is that a bullet, which pierced his mouth, lodged in the heat-center of the brain.

SOUTHERN STATES.

Johns Hopkins University.—Dr. William H. Welch and Dr. William Osler, of the Johns Hopkins Medical School, have been named as possible candidates for the presidency of the university.

The Smoke Nuisance.—On the oath of Dr. R. L. Lynch, an inspector of the health department of the District of Columbia, 6 warrants charging violations of the smoke law have been issued.

University of Texas.—Since the storm, improvements and temporary repairs to the amount of \$25,000 have been made on the buildings of the medical branch at Galveston. The board of regents will ask the next legislature for an appropriation of \$60,000 to permanently restore the buildings of the medical department and to resupply laboratories that were destroyed. They will also ask for \$45,000 per annum for the support and maintenance of the medical department. The outlook for the year is favorable, there being 150 students present the first day.

MISCELLANY.

Condition of Alaskan Indians.—Dr. Sheldon Jackson, who cruised along 1,000 miles of coast in Behring Sea and the Arctic Ocean, reports an appalling condition among the natives from inroads of grip, measles, and pneumonia.

Industrial School for Hawaiian Lepers.—A band of Franciscan Sisters under the leadership of Mother Ann M. Schilling, of Syracuse, N. Y., are about to leave San Francisco for the Hawaiian Islands to establish an Industrial School in the leper settlement at Molokai and devote their lives to this work.

Emergency Rations.—Captain Fountain and Captain Foster have returned to Fort Reno, O. T., after an absence of 10 days testing the emergency ration which was compounded at Passaic, N. J. Enlisted men of the detachment say that the ration just tested is not as good as that tested by the first detachment. It is seasoned too highly to be palatable any length of time. The tea ration serves well for a few meals, but does not suit as well as the chocolate ration. A ration prepared in Chicago will be tested during the next 10 days. The board will devote a week to testing again the ration of the 3 which proves most satisfactory.

Obituary.—GEORGE H. BRIGHT, of Richmond, Va., November 20, aged 64.—HIRAM W. RITTER, of Soudertown, Pa., October 9, aged 46.—H. A. HAMILTON, of Marysville, Ia., November 26.—ROBERT ACTON, of New York, November 20, aged 35.—EDWIN POTBURY, JR., of Georgetown, D. C., November 20.—A. L. A. "	Osaka . . . Oct. 8-23 . . .	3	

Contagious Diseases.—In Washburn, Wisconsin, 22 cases of smallpox of a mild type are reported. The Michigan State Board of Health has detailed a physician to go to the upper peninsula to take charge of an aggressive campaign against smallpox. The situation there is pronounced critical. Two members of the Walker Theatrical Company were recently taken to the Municipal Hospital in Pittsburgh suffering with smallpox. The health authorities at once went to the theater and vaccinated the entire troupe of 40 actors. A case of the disease has been discovered in King's County Hospital, Flatbush, N. Y., in a negro patient who had not been outside the institution since May. Decatur, Nebraska, and its vicinity is quarantined, having over 100 cases. A mild

type has been prevalent there for 6 months. At Naniamo, B. C., an epidemic has been reported, and the disease again prevails among the Indians near Rolla, N. D. Sir Alfred Milner, the British High Commissioner, has announced that all ports on the East Coast of South America between the 10th and 40th parallels are infected with plague, and a fatal case is reported from Merida, Yucatan. The State Board of Health of Jackson, Mississippi, has received official notice of 2 cases of yellow fever and one death at Brook Haven, about 60 miles from Jackson. In Havana 56 cases of yellow fever are now under treatment and the disease is reported as rapidly abating. The captain of the steamer *Adler*, which arrived in New York recently from Port Simon, died of yellow fever and was buried at sea.

Foreign News and Notes.

GREAT BRITAIN.

Women Physicians in London.—In London alone there are now 85 medical women. Some of these hold posts in dispensaries, hospitals, infirmaries, as ophthalmic surgeons, assistant anesthetists, medical examiners, inspectors and lecturers.

Arsenic Poisoning.—Manchester is suffering from an epidemic of arsenic poisoning; at least 1,000 cases are known. It was found to be confined to beer drinkers, and an analysis of some of the beer revealed arsenic enough to account for the symptoms of poisoning.

Royal Army Medical Corps.—The Secretary for War having granted the President of the Royal College of Surgeons in Ireland two nominations for commissions in the Royal Army Medical Corps, Mr. Myles has nominated Mr. J. Langdale Jones and Mr. G. Faber Sheehan, licentiates of the College and past pupils of the College School, for the vacancies.

CONTINENTAL EUROPE.

Typhus fever is epidemic in Copenhagen. On November 20, 20 new and serious cases were officially reported.

Quails are said by high medical authorities to be a source of typhoid infection in Russia. A local paper says: "Hereafter let all quails imported from Russia be accompanied by a certificate that they have been sterilized."

Women in the Profession.—Prof. Friedrich Schanta, of Vienna, in a recent address to the students attending his course in gynecology, expressed his opinion that law and other professions should be opened to women, as too many of them crowd into medicine. Of every 100 female medical students, he said, only 33 became physicians, the others being incapacitated by the horrors of the dissecting-room and other impediments.

MISCELLANY.

Malaria in India.—An alarming spread of malaria is reported in the districts of Ferozepur, 38 deaths having occurred in one day. The rural population cannot find men to work in the fields, as the laboring classes are the greatest sufferers from the disease.

Precautions Against Disease in Greece.—It is reported that the personal baggage of a traveler when not accompanied by the owner must on its arrival at any port in Greece be accompanied by a certificate of origin, or a certificate from the health authorities of the port from which the baggage was shipped.

Gift to Hospital.—It has been announced that Raja Jyoti Prasad Gorga, of Moisalad, has offered a sum of Rs. 5,000 towards the construction of an operating room for the Midnapur hospital, in order to perpetuate the occasion of the Lieutenant-Governor's recent visit to Midnapur, and has expressed the desire that the room be called "The Woodburn Operating Room."

1.—Duckworth reports the case of a man, aged 36 years, who during the course of **pernicious anemia** complained of a feeling of swelling, weakness and numbness in both legs and in the hands, but no wasting. There was complete loss of sense of position; nearly complete anesthesia below a line encircling knees beneath the patella but dipping down below the popliteal space in a loop over the calf in "small sciatic area." The kneejerks were equally exaggerated; there was no ankle-clonus. During the course of the disease loss of rectal control and difficulty in micturition developed. At the necropsy the diagnosis of pernicious anemia was confirmed. There was a well-marked iron reaction in the liver and the kidneys. There were fatty kidneys and there was also softening of lumbar portion of spinal cord, which accounted for the **spinal symptoms**. Gallstones were also present. [J.M.S.]

4.—Tooth calls attention to the extreme difficulty that must attend all efforts to prevent the spread of typhoid fever by sanitation only. It is, therefore, with the greatest interest that we turn to the subject of the **establishment of an artificial immunity** in the individual soldier. Twenty-four noncommissioned officers, orderlies, and servants of the Portland Hospital, and 4 of the medical staff, were inoculated on the voyage out. Of the orderlies 9 had enteric fever subsequently, 2 of whom had refused inoculation and one of the latter died. Of the inoculated cases 5 had the disease lightly, and 2 rather severely. Of 231 patients, 53 had been inoculated at home or on the voyage out, and of them 3 died, making a percentage of deaths among the inoculated of 5.6%; 178 had not been inoculated, of whom 25 died—that is, a mortality among the noninoculated of 14.0%. The general mortality was 12.1%. The above figure comprise officers and men. Thirty-three officers were admitted with enteric fever; of these 21 had been inoculated. Only one of these officers died and he had not been inoculated. Inoculation as a preventive is still on its trial, but it has not had a fair trial. [J.M.S.]

5.—Cummins describes a method for the **effective sterilization of excreta from typhoid patients**. A 30-gallon iron "jackpot," containing 2 gallons of 1 in 20 carbolic solution, was kept boiling day and night, and the feces and urine were emptied into this solution as soon as they were passed; there was practically no smell; the vapor had a heavy odor redolent of carbolic acid, but at 1 or 2 yards distance it was scarcely perceptible. The apparatus has been in use for nearly 2 months, during which time over 200 cases of enteric fever have been under treatment. No case of enteric fever has occurred among the orderlies employed in nursing and for pioneer work. A control experiment was made by inoculating one nutrient agar tube from the contents of a bedpan that the attendant was about to empty into the cauldron. The stool was poured into the cauldron, and 10 minutes after 5 nutrient agar tubes were inoculated from the contents of the pot. All the tubes were incubated at blood-heat for 24 hours. The tube used as a control showed about 100 well-marked colonies, while the 5 infected by the contents of the pot showed no sign of bacterial growth. [J.M.S.]

6.—Watkins Pitchford during his service in South Africa had little opportunity of **treating dysentery** in its initial stages, and it is probably on this account that the treatment by saline aperients has met with little success. The much credited ipecacuanha cure also proved disappointing. The tincture of "Monsonia ovata" appeared to produce no effects whatever except nausea and depression. Greater success attended the use of mercury perchlorid in mixture with bismuth and opium. Izal combined with bismuth and chlorodyne gave a most satisfactory result. Milk was found to be an unsuitable diet for dysentery patients. Beef tea and bread with butter satisfy, and leave a residue which appears to cause but little colic or rectal irritation. Post-mortem observations show that great risk must frequently accompany the giving of rectal injections, especially when combined with abdominal massage. The coexistence of enteric fever with dysentery was more than once unexpectedly disclosed in the mortuary tent. [J.M.S.]

7.—Pearce reports the case of a man, 33 years of age, who complained of feeling tired and exhausted for several days, and who had frequently had to come in to rest while pursuing his ordinary avocation on his farm. When seen by the author, the patient's temperature was 102°, his tongue was dry and baked, his eyes were glassy, and his face was slightly flushed. His abdomen was swollen and tympanitic. The area of hepatic dulness was almost entirely gone, and there was great pain on pressure over both the liver and the spleen. The urine contained a trace of albumin, and was highly colored. Four days later violent hemorrhage occurred from the nose; the patient's skin was intensely jaundiced; numerous small hemorrhages occurred under the skin all over his body, and he vomited several times. The patient gradually grew weaker and finally died. A diagnosis of **acute yellow atrophy** of the liver was made, although there was no autopsy. [J.M.S.]

8.—Anderson reports a case of **acute yellow atrophy of the liver** which was confirmed by necropsy. [J.M.S.]

9.—On September 27, 1900, 7 members of a family of 8 living in a small farm-house partook of supper at 9 P.M., which consisted of cold stewed goose giblets to which had been added scraps of goose and slices of beef. During the night following the patients were all taken violently ill with symptoms that clearly indicated some kind of **irritant poisoning**. Two of the patients died, and a necropsy made on one of them showed intense congestion of the intestines and stomach. No indication of any special poison was found. Packer was unable to find any poison either in the remains of the supper or in the viscera of the deceased woman. [J.M.S.]

10.—Morgan reports the case of a man, aged 43 years, who was suffering from **lead poisoning**. It was learned that the patient called daily for his pint of beer before breakfast and that he was usually the first to get the "dra" through one of the leaden pipes that led from the cask. A pint of beer drawn the first thing in the morning from these pipes was found to contain lead in solution. The patient's urine also showed the presence of lead. The patient finally fell down in a fit and lingered a few hours before he died. [J.M.S.]

11.—Durno reports a series of cases of **glandular fever**. The patients were an adult and several children. The ages of the victims ranged from 2½ to 13 years. There were no premonitory symptoms, the disease being ushered in by head-

ache, nausea, vomiting, and pain in one side of the neck. The temperature ranged from 100° to 105°. From 12 to 36 hours after the onset there appeared a distinct and definite swelling of the affected side of the neck that proved to be a group of lymph glands. Except in the very mild types, there was well marked hepatic tenderness and increased dullness. In a few cases there was tenderness over the spleen. In two cases hemorrhagic nephritis was developed as a complication. About the end of the first week very offensive diarrhea with slimy stools, varying in color from pale yellow to dark green, seemed to mark a crisis. Acute anemia developed very rapidly. Convalescence in the majority of the cases started between the second and the third week of the illness, was very protracted, and even in the mild types was out of all proportion to the severity of the attacks. There were no deaths. An important element in the treatment is to maintain as thorough an antiseptic state of the mucous membranes of the throat and pharynx as possible. In a few of the earlier cases this precaution was neglected, and it was in 2 of these that otitis media occurred. Either a spray of 1 in 5,000 mercuric perchlorid or a swab of glycerin and carbolic acid was used to disinfect the throat. [J.M.S.]

12.—Hatch has observed an "hepatic odor" in cases of abscess of the liver and by this odor alone has been able to diagnose several cases. It is especially well marked when the patient is confined in a small room, while in large, airy wards it is only observed about the bed. [W.S.N.]

13.—Lewtas was called to operate on a case of intestinal obstruction and repeat it within 7 months. The same conditions were found at both operations; about 6 inches of the bowel was constricted to the diameter of a lead pencil; no cause could be found and it was presumed to be spasmodic. Each time the mass above the constriction was simply pressed through; the abdomen was then closed and the patient made a rapid recovery. [W.S.N.]

14.—Taylor, on being called to a case of diphtheria, gives a good dose of calomel, paints the throat, tonsils, back of pharynx, and uvula well with the tincture of iodine, and advises the repeated inhalation of the tincture of iodine in hot water, about one teaspoonful of the tincture in a quarter of a pint of hot water, for about 5 minutes at a time every half hour or so. [J.M.S.]

15.—Carr reports the case of a woman, aged 35 years, who had eaten some codfish. Almost immediately afterwards she complained of discomfort about the eyes, and itching of the face, and a marked urticarial rash developed over the upper extremities, face, and upper part of the trunk. This was soon followed by the appearance of a large bullae on the lobes of both ears, and on the wrists and forearms, simulating closely the effects of a scald. The eruption also severely affected the mouth and the pharynx. The highest temperature reached was 103.6°. The itching was very great at first, giving way later to severe burning. [J.M.S.]

16.—In 1898 Jones reported a case of hemophilia in a girl of 8 years. Ordinary treatment failed to have any effect. On May 1, 1900, the author commenced to give 4 minims of liquor thyroidei 3 times a day. There was a slight hemorrhage a fortnight later, but there has been none since. [J.M.S.]

17.—Adams gave a drunken woman a hypodermic injection containing $\frac{1}{2}$ grain of apomorphin. In about 20 minutes she was quietly sleeping. [J.M.S.]

21.—Croft reports a cesarean section in a case of a contracted, rickety pelvis, which resulted favorably, both mother and child being well when seen 4 months later. [W.K.]

22.—Taylor reports the case of a Hindoo girl suffering from urinary calculi lodged in the vagina. After a slight incision of the vulva, a stone about the size of a walnut was removed with lithotomy forceps. Back of this were 4 others packed in the vaginal fornices. They were round in shape, largely composed of lime salts and weighed altogether 2 ounces and 100 grains. Sloughing continued and on the sixth day another stone (1 ounce and 45 grains) was removed, the patient dying a few days after. [W.K.]

1.—Some of the substances classified as urinary pigments are merely colored products formed by the action of reagents upon constituents of urine that are themselves colorless. Among these are urochrome and the indigo pigments. Of the true urinary pigments some are excreted either wholly or in part, as colorless or faintly colored parent substances known as "chromogens," that quickly become converted into their colored derivatives when the urine is exposed to light and air. Colored substance may enter the alimentary canal in articles of food, in sweetmeats, or in medicines, and may be thence absorbed and excreted either altered or unaltered by the kidneys. Certain pigments are normal constituents of the body, but only find their way into the urine under morbid conditions, such as hemoglobin, bilirubin, biliverdin, and melanin. There is a group of coloring matters that may claim to be urinary pigments in a more special sense, seeing that they may all be present, if only in traces, in the urine of persons who may fairly be considered to be in normal health. Urochrome, urobilin, hematoporphyrin, and uroerythrin belong to this class. Urochrome is the most abundant of the urinary pigments, and to it the familiar yellow color of normal urine is probably entirely due. Urobilin only occurs in very small amount in normal urine and wholly in the form of chromogen. Hematoporphyrin is present in mere traces in normal urine and often in increased quantity in disease. Uroerythrin may appear in small amounts as the result of very trifling deviations from perfect health. In morbid urines it is often abundantly present, and it is chiefly conspicuous as the coloring matter of pink urate sediments. The chief seat of the formation of urobilin is undoubtedly the intestinal canal. Increased excretion of the pigment, evidenced by a dark absorption-band seen when the urine is examined with the spectroscope, is a very common phenomenon in disease, and we may distinguish between cases in which the band is seen for only a few days in succession and those in which it is present over a long period. A distinction may also be drawn between cases of what may be called "pure urobilinuria" and those in which uroerythrin and hematoporphyrin are also present in excess. In febrile disorders of almost every kind temporary urobilinuria may be met with, the duration of which usually corresponds with that of the pyrexia. In diseases of the liver the urobilinuria is usually persistent, as is well seen in cases of cirrhosis, malignant disease, or passive congestion secondary to cardiac or pulmonary troubles. In diseases attended by excessive hemolysis, and during the absorption of extravasated blood, there is apt to be conspicuous urobilinuria, and, unless complications are present there is no corresponding increase of uroerythrin or hematoporphyrin. The occurrence of persistent urobilinuria in pernicious anemia supplies a diagnostic sign of real value and affords an indication of the progress of the case. In association with it, Garrod has observed a marked excess of urobilin in the feces. When blood-extravasations are being absorbed a temporary urobilinuria is apt to occur in a day or two after the occurrence of the hemorrhage, and this

again may prove of service in the diagnosis of deep-seated hemorrhage such as pelvic hematoceles. Diminished excretion or absence of urobilin from the urine may be due to diminished formation of bile-pigment, as in chlorosis, phosphorus poisoning, or acute yellow atrophy of the liver; to suspension of urobilin formation in the intestine as in typhoid fever with green stools; as well as to occlusion of the common bile-duct. Viglezo suggested that renal permeability has an important influence upon the excretion of this pigment, and it is a clinical fact that albuminuria and urobilinuria very seldom coexist. There is, moreover, experimental evidence in support of this view. In normal human urine, hematoporphyrin is present in minimal quantities, as can readily be demonstrated by appropriate methods. In many morbid urines it is found in larger but still small amounts and under exceptional circumstances, and especially as a result of the administration of sulfonal, it is much more abundantly present in urines which have a deep, port-wine tint. However, such urines owe but little of their peculiar color to this pigment. It is also present in the feces, and it may be extracted from meconium. In a case of sulfonal-poisoning, A. E. Taylor and J. Sailer have recently recovered it from blood collected postmortem. Hematoporphyrin has at least 4 characteristic groupings of absorption-bands for its identification under different conditions. The amount present in urine is usually so small that the bands are quite invisible on direct spectroscopic examination, or are so faint that they can only be recognized by a trained eye. Garrod believes that we are justified in concluding that the hematoporphyrin of the body has hemoglobin for its parent substance, and is isomeric with bilirubin. Seeing, then, that at least the greater part of the hematoporphyrin of the body is derived from human sources, it is a natural supposition that its excretion in excess is an indication of increased hemolysis. Experiments seem to show, however, that there is no necessary connection between excess of hematoporphyrin in the urine and excessive hemolysis. [J.M.S.]

2.—Hale White has studied the records of cases of empyema following lobar pneumonia which have been treated of late years in Guy's Hospital, London. Altogether he has found 45 cases of this kind. It is impossible to state with accuracy the percentage of cases in which pneumonia is followed by empyema, but out of 325 consecutive cases of empyema in the medical ward of Guy's Hospital 12.6% followed a lobar pneumonia. From his experience in the treatment of this condition he concludes that it is very unlikely that simple aspiration will cure any case of empyema arising from pneumococcus infection. In a certain number of cases it appears to be curative, but it seems wiser to evacuate even small empyema by incision. The amount of pus found in his cases was quite variable. In one case 170 ounces were present; in another 100 ounces were secreted in one and a half days. Of the 45 cases reported 13 died, giving a mortality of 29%, which is considerably higher than that given by some authors. [M.B.T.]

4.—Bryant reports two cases of acute hemorrhagic pancreatitis. In the first case the history of previous attacks of abdominal pain and indigestion spreading over several years and the acute onset of severe abdominal pain after a late meal of pigeon pie seemed to point to perforating gastric ulcer as the most likely explanation of the patient's condition. A satisfactory elucidation of these attacks of pain was found at the necropsy in the gallbladder, which contained several calculi. In nearly all of the cases of pancreatitis which have been examined bacteriologically *Bacillus coli communis* has been found; the invasion of the pancreas by this organism may have been the cause in the case reported. The finding of fat necrosis outside the peritoneal cavity in the mediastinal and pericardial fat in the second case was very unusual. The previous history of abdominal pain and indigestion and the acute onset with pain suggested perforating gastric ulcer as the most likely diagnosis to explain the symptoms complained of. There was a large collection of clear, bile-stained, serous, sterile fluid found in the peritoneal cavity at the time of the operation; but no fat necrosis was found and the pancreas did not appear to be enlarged. At the necropsy a biliary calculus was found, but it was small and was not obstructing the flow of bile. The tissues in the neighborhood of the bile-passages and pancreas had a swollen and sodden appearance and were all very deeply stained with bile, but there was no abnormal opening

in the gallbladder, cystic duct, hepatic duct, or common bile-duct which could allow of the escape of this fluid. There were numerous areas of fat necrosis in the peritoneum and hemorrhagic pancreatitis. [J.M.S.]

5.—Guerrini has studied the changes in the liver and the kidneys produced by fatigue. In the kidney the grosser modifications of structure are in the cells of the convoluted tubules and of the ascending part of the loop of Henle. The modifications of structure are, naturally, in relation with the degree of fatigue undergone by the animal. The protoplasm loses its usual aspect and becomes homogeneous and granular. It appears that the cellular body enlarges, so that the borders of the cells that surround the opening of the canals fray out and break and the cellular protoplasm shows rarefied points, vacuoles and cracks, and finally crumbles into a fine detritus that collects in the opening of the tubules. In the midst of this detritus normal nuclei are sometimes found, sometimes lumps or granulous masses that stain like the nuclei. The minute modifications of structure of the liver-cells are much less than those of the kidney-cells. All the cellular protoplasm appears homogeneous, cloudy and granular. The cellular body enlarges and the edge between the cells becomes uncertain and sometimes disappears altogether. Sometimes the little biliary canals are evidently compressed, whereupon the protoplasm of the liver-cell appears rarefied, full of knots, spongy, and very dark from biliary pigment. [J.M.S.]

6.—Hume reports 11 operations for perforated gastric ulcer, all in women, which he has performed during the past 7 years at the Royal Infirmary at Newcastle-upon-Tyne. A patient, 20 years old, was operated upon 48 hours after perforation. The ulcer was situated on the anterior wall near the pylorus. The peritoneal cavity was flushed and drained; death resulted. In a second case a patient, aged 28, was treated in the same manner and death resulted. Further particulars are not given. In a third case a patient of 30 was operated upon 48 hours after perforation. The ulcer was situated on the anterior wall near the cardia; death resulted. In a fourth case, a patient of 23, 5½ hours elapsed between perforation and operation; the ulcer was situated on the greater curvature and death resulted. In a fifth case occurring in a girl of 16, 1½ hours elapsed between perforation and operation. Perforation on the lesser curvature; recovery. In a sixth case, a patient of 18, operation 43 hours after perforation which was in the anterior wall. Death resulted. In a seventh case, occurring in a girl of 19, 6 hours elapsed between perforation and operation. The perforation was on the anterior wall. The patient recovered. In an eighth case, occurring in a girl of 18, operation 28 hours after perforation. The perforation was in the greater curvature. The peritoneal cavity was wiped dry, no drainage was employed. Recovery resulted. In a ninth case, a patient of 26 was operated upon 21 hours after perforation which was located in the pylorus. The peritoneal cavity was sponged, no drainage was employed. Recovery resulted. In a tenth case occurring in a patient of 18, 7½ hours elapsed between perforation and operation. The perforation was situated in the posterior wall near the lesser curvature. The peritoneal cavity was treated as in a previous case and recovery resulted. In an eleventh case occurring in a patient of 27, 7 hours elapsed between perforation and operation. The ulcer was situated at the anterior part of the cardiac end of the stomach and the peritoneal cavity was flushed and drained and recovery resulted. In all of the cases the edges of the ulcer were not excised, but the opening was closed by a double row of Lembert catgut sutures and omentum was laid over the line of suture when possible. Hume believes that the treatment of the peritoneal cavity should depend upon the amount of extravasated stomach-contents and the general effusion. Thorough flushing he believes to be the best treatment, provided there is a large amount of stomach-contents and effusion in the peritoneal cavity. Sponging is preferable in case there is only limited and local extravasation. [M.B.T.]

7.—The case of a boy of 17 is reported, from whose forehead an anthrax pustule was excised successfully. No bacteriologic examination was made. [M.B.T.]

8.—Hepworth gives the history of a woman living in London, who consulted him for amenorrhea. He could find no physiologic or pathologic cause for it, and advised her to see him again after a 6 weeks' visit to the country, at which

time she returned to say that the menses were regular while in the country. After several repetitions of a similar experience, he has recommended her to leave London and take up her residence in the district in which she lived prior to her marriage. [W.K.]

10.—A man of 60 years of age had noticed a small pimple over the sixth rib just external to the apex of the heart 3 months previous to admission to the hospital. This pimple broke and discharged as the result of friction of his clothing. A lump then appeared at the situation of the pimple, which gradually grew to the size and shape of a hen's egg. It was firm at the periphery, soft and semi-fluctuating in the center; firmly adherent to the rib. The rib was cleared at a point $\frac{1}{2}$ inch beyond the limits of the tumor on each side and the one with the tumor was excised. In doing this the left pleural cavity and the pericardium were freely opened. The heart bulged from the opening and air entered the pleural cavity, causing collapse of the lung. The wound was closed with interrupted silkwormgut sutures. After the operation there was rise of temperature for several days and evidence of bronchitis. The dressings were blood-stained. There was considerable dyspnea and frothy expectoration. Gradual recovery followed and the patient left the hospital with the wound soundly healed. Pathologic examination showed the growth to be a periosteal spindle-celled sarcoma. [M.B.T.]

New York Medical Journal.

November 24, 1900. [Vol. Lxxii, No. 21.]

1. Rational Physical Training for Women. GEORGE ALEXANDER SAXE.
2. The Etiology of Eczema, with Reference to Recent Views as to its Parasitic Origin. L. DUNCAN BULKLEY.
3. Postoperative Hemorrhage. A. H. CORDIER.
4. Spasmodic Wry-neck and its Treatment; Report of Two Cases with Recovery. WILLIAM M. LESZYNSKY.
5. The Pathology, Diagnosis, Special Prophylaxis, and Treatment of Tuberculosis of the Middle Ear. SEYMOUR OPPENHEIMER.

2.—After an exhaustive study of the etiology of eczema, Bulkley confesses that the real cause of the disease is not yet known. The most that has been shown in regard to parasitism is that some of the microorganisms that exist most abundantly on the skin cease to be saprophytic when that organ is diseased. [J.M.S.]

3.—Cordier in diagnosing postoperative hemorrhage finds the operative history a great aid. The symptoms of shock and those of hemorrhage are very similar and in suspected cases cutting a single stitch in the incision will tell. The surgery must be quick and decisive. Cases in which bleeding is expected, the tube (drainage) should be used. (It is not only a sentinel but has a direct hemostatic power, as blood will not coagulate quickly nor firmly in an air-tight peritoneal cavity.) Large quantities of normal salt-solution will save many patients and should be given by rectum and intravenously. Strychnin, belladonna, etc., will not control bleeding and the surgeon should do what his surgical conscience tells him is right. [W.S.N.]

4.—Leszynsky by prolonged rest in bed, massage, special exercise, and hypodermic injections of atropin into the affected muscle, has been able to cure 2 cases of spasmodic wry-neck, and believes if routine treatment were adopted earlier, many cases would recover without surgical interference. He does not regard the disorder as analogous to the occupation-neuroses, but rather one of functional origin. The muscular hyperkinesis is apparently due to irregularity in the action of the cortical cerebral cells innervating the muscles of the neck. [W.S.N.]

5.—Oppenheimer believes the diagnosis of tuberculosis of the middle ear for syphilis, lupus, etc., can only be made by examining the discharge or a piece of tissue for bacilli. He divides them into 3 classes: (1) Tuberculosis of the middle ear in an apparently healthy person; (2) tuberculosis of the middle ear, secondary to it elsewhere; (3) general tuberculosis with a nontuberculous otorrhea. When the throat is the seat of disease, special prophylactic precaution should be taken to save the ears, as the eustachian tubes open up a very good avenue for infection. Treatment

consists in removing all diseased tissue, then applying some antiseptic powder like iodoform in conjunction with tonics. [W.S.N.]

Medical Record.

1. Apparent Tumors of the Abdomen. MAX EINHORN.
2. Myasthenia Gravis, with Clinical Report of Case. SANGER BROWN.
3. Notes on Typhoid Fever, with a Report of 15 Cases. D. E. KEEFE.
4. The Value of Thermal Carbonated Saline Baths in Gynecology. S.W. BANDLER.
5. A Sample Method of Writing Prescriptions for Children. MAX HUHNER.
6. A Method for the Determination of Eye Defects in School Children, with a Report of 1717 Examinations. LOUIS C. DEANE.

1.—Einhorn first reviews the scanty literature on apparent tumors of the abdomen. In discussing the subject he does not include swellings caused by prolapse of any organ, but refers to the tumors which are found either directly in the epigastrium or in the right or left hypochondrium and are not in any sense neoplasms. He also excludes phantom tumors so far as this term applies to cases of localized meteorism. In cases which he describes there is found a resistance, or a mass discovered by palpation or even inspection, the mass having rather a smooth surface and frequently pulsating. The size is between that of a hen's egg and of a man's fist. Upon light percussion there is always dullness over the area of the mass. In 6,045 cases observed by Einhorn there were 42 instances of apparent tumor of the abdomen, 34 of these occurring in women. They are, therefore, not very frequent. He describes some characteristic cases, and then states that an apparent tumor may be produced by prolapse of the left lobe of the liver, by exposure and thickening of the abdominal aorta, by local hypertrophy of the abdominal muscles, or possibly by adhesions about the small curvature of the stomach. He has not had occasion to make an autopsy in any of these cases, as they usually do well under proper treatment, but he feels that there is no doubt of the correctness of the suggestions which he makes. The apparent tumor may be determined to be the left lobe of the liver if it is directly below the ensiform process, and if instead of liver-dullness above, where it should normally be, we find more or less resonance or tympany. That the mass felt is the aorta may be determined by discovering its vertically elongated shape and its strong pulsation. Localized hypertrophies of the abdominal muscles are determined by observing their superficial position, and the fact that they lie to one side of the linea alba, and usually give a horizontal resistance an inch or so in breadth by 2 or 3 inches in length, and have a flat almost smooth surface. Adhesions are difficult of diagnosis. Apparent tumors are distinguished from real tumors by their smooth surface, and the fact that they vary in distinctness from time to time. They are usually associated with a high degree of enteroptosis, and if malnutrition exists it has been present for a long time and is not actively progressive. The diagnosis is usually easy, but in some cases is exceedingly difficult, and it may be necessary to observe the case for a long period. Two points which he emphasizes in treatment are, to direct the attention of the patient away from the mass, and to give sufficient nourishment. [One cause of apparent tumor that is undoubtedly not very uncommon in cases of enteroptosis is palpable pancreas. D.L.E.]

2.—The case reported was that of a woman of 29 whose previous history was good excepting that she was of somewhat nervous temperament. Sixteen months before the report she had overtaxed herself, and found that very profound muscular exhaustion followed upon relatively slight exertion. Diplopia and ptosis soon became marked, her voice became nasal and articulation poor, the changes in the voice apparently being due largely to weariness of the tongue. There was some palpitation; the masticatory muscles tired readily, the mucous membrane of the mouth and nose were often uncomfortably dry, the hair and scalp were dry and she had lost much hair. There was no distinct mental

change, no confusion of ideas, and no evidences of ordinary neurasthenia. Voluntary motion was present, but the strength was much reduced. There was no muscular atrophy or disorder of sensation or evidences of hysteria. The examination of the eyes showed nothing but an astigmatism. The visual fields were not tested nor was any attempt made to exhaust the kneejerks by a repetition, and electric tests were not used. There was no incoordination. A description of the condition of **myasthenia gravis** is given, mentioning as the chief characteristics the fact that some severe disease has often preceded, that the affection is of gradual onset, that one of the earliest signs is weakness of some of the muscles supplied by cranial nerves; that the most characteristic symptom is profound exhaustion upon slight exercise, the muscular symptoms being bilateral. Ptosis and diplopia are very common early signs, there is often a feeling of aching and stiffness in the tongue after eating or speaking, the voice becomes nasal, and there is inability to support the head. A very characteristic symptom is that the muscles react normally to electricity but are readily exhausted by the faradic current; after rest they respond again. Atrophy is not present, there is no disturbance of the sphincters, and no incoordination. Brown believes that the disease is produced by a toxin developed in the body. The prognosis is bad, 23 of 60 cases referred to having ended fatally, with an average duration of 1½ years. Death is commonly caused by paralysis of the respiratory muscles. One case has been reported which ended fatally in 4 months. The treatment suggested by Brown is the hypodermic use of strychnia nitrate. [D.L.E.]

4.—Bandler considers **hydrotherapy a powerful curative method**, since thermal and mechanical processes are the normal stimuli which arouse, strengthen and regulate our organic functions in a physiologic way. A warm full bath causes an increase in the rapidity of the pulse, which persists after the bath. Such a bath can through weakening of the venous tonus cause an increased resistance in the minor circulation, whereby, in spite of increased work on the part of the heart, no bettering of the circulation results. This is a weakening influence, since the heart is sufficient only when it is able to force the blood to the most distant organs, in whose capillaries alone tissue metabolism takes place. A warm bath causes usually no increased demand for nutrition and exerts no stimulating effect on the central nervous system. If carbonated water is used, the action of CO₂ is to produce a feeling of warmth, and a dilation of the capillaries of the skin and of the peripheral vessels. After a bath the CO₂ causes a feeling of exhilaration, provided the amount of CO₂ and the duration of the bath be not too great. The action of thermal carbonated saline baths brings about the following results: (1) Slowing of the pulse and respiration; (2) increased oxidation; (3) increased diuresis; (4) a saving of phosphoric acid; (5) rest and protection for the heart; (6) regulation of the circulation and a subsequent strengthening of the heart through increased tonus of the entire circulatory system, and through the removal of congestions; (7) an increase in the number of red blood-cells; (8) a building up of healthy tissue; (9) an increased demand for nutrition; (10) a stimulation of the entire nervous system, especially the trophic centers; (11) the removal of congestion; (12) the resorption of exudates. Bandler believes that the results obtained justify him in claiming for the carbonated saline baths a power of resorption too valuable to be underestimated, a method which at the time benefits the general state to a decided degree, and which acts by increasing the natural and effective functions of the body, and in toning up those pelvic structures which depend so decidedly for their elasticity and blood-supply on the condition of the body generally. [W.K.]

Medical News.

1. Edema Bullosum Vesicae. FREDERIC BIERHOF.
2. The Operative Treatment of Ugly Ears. JOHN B. ROBERTS.
3. The Hydratic Treatment of Tuberculosis. J. H. KELLOGG.
4. Absorption, Motility, and Digestive Power of the Stomach. A. E. AUSTIN.
5. The Nature Treatment of Tuberculosis. R. O. BEARD.

1.—Bierhoff cannot ascribe any diagnostic value to

edema bullosum vesicae except that it is a sign of some inflammation around the bladder that has involved the wall of that organ. It appears as a number of clear vesicles varying in size from a small seed to a pea, with small, white particles floating between them, probably pieces of those that have ruptured, and present the appearance of an hydatid mole. A condition resembling this is cystitis papillomatosa, but they are vascular loops and are smaller than the vesicles. [W.S.N.]

2.—Roberts thinks that more **ugly ears** would be brought within the physiologic limit by persons possessing them, if the character of the operation was more generally known. [W.S.N.]

3.—Kellogg, in the third instalment of his paper on the **treatment of tuberculosis with water**, gives the notes of 8 cases, all of which were either cured, or so greatly improved that the treatment could be regarded as brilliantly successful. One of these patients was in a late stage of the disease, and had a cavity in the lower portion of the left lung. He summarizes the essential features of the treatment as follows: the graduation of the general and local applications to the skin, in regard to intensity, duration and frequency, always keeping within the limits of the patient's ability to react; and the application of hot and cold compresses for the relief of pain and cough, and the strengthening of the tissues. He thinks a dry, elevated climate is an exceedingly important adjunct to the hydratic treatment. [J.S.]

4.—Austin, believing that the **residual albumose peptone** in the stomach-contents may be taken as an evidence of the **absorptive powers** of that organ, has undertaken to devise a method for estimating this albumose peptone in the stomach-contents removed 1 hour after a test-meal. The amount of albumen in the test meal is not stated, but it has been given in a previous article. The results show that when .6 gm. or more remain in the stomach-contents, absorption is deficient. A somewhat similar method is employed for testing the digestive power of the stomach, that is, the albumose peptone is estimated in the stomach contents, a definite amount of albumen added, and after a sufficient interval, the amount of albumose peptone again estimated. The difference between the two results represents the amount of digestion that has taken place in the interval. The calculation is expressed in terms of the number of parts per 1,000 of its volume of albumose peptone. It varies apparently, in normal persons, from 1 to 7 parts per m. Austin believes that no examination of the stomach is complete without testing its absorptive power, and that the method he suggests is as good as any other. Retardation does not occur in cases of gastric insufficiency without dilation. The digestive power should always be tested. [J.S.]

5.—Beard believes that as the essential elements in the **open-air cure of tuberculosis** are pureness and dryness of the atmosphere, and not any particular altitude, the State should set apart large tracts of land suitable for the purpose of sanatoria for consumptives. He also thinks that much would be gained by the development of suburban life, in order that the segregation now taking place in large cities might be avoided. Another important feature in the treatment of this disease is rest. [J.S.]

Boston Medical and Surgical Journal.

1. Diphtheria Bacilli in Healthy Throats and Noses, with Report of Cases. FRANCIS P. DENNY.
2. Chronic Diffuse Interstitial Nephritis. CHARLES J. ENEBUSKE.
3. A New Spinal Jacket. EDWARD A. TRACY.
4. Some Observations on Renal Casts. WALTER E. TOBIE.

1.—After a study of the frequency of the occurrence of **diphtheria bacilli in the noses and throats of healthy individuals** Denny concludes: (1) That diphtheria bacilli are seldom found in the throats of those who have not been exposed to diphtheria; (2) that bacilli are more frequently found in those who have been exposed, especially in persons living under poor hygienic conditions or in institutions; (3) that the one condition of institution life that favors the growth of the bacilli in healthy throats is

the living together of a large number of persons in a limited air-space; (4) that healthy individuals with virulent bacilli in their throats can spread the disease. They are just as dangerous as mild or convalescent cases of diphtheria, and ought, therefore, to be detected and isolated; (5) and that cultures should be made among those who have been exposed to diphtheria: (a) by physicians among the members of the family who have been exposed, (b) by inspectors in the schools, (c) by health-officers under any circumstances when they think the disease is being or may be spread by such individuals. [J.M.S.]

3.—Tracy recommends wood-pulp as a material for spinal jackets instead of plaster of paris. It is lighter than plaster; cleanly, rigid and durable. He has employed this material with satisfactory results for 5 years. [M.B.T.]

4.—Out of 200 specimens of urine, Tobie found that 27 contained casts without albumin. He found this condition common in cases of carcinoma. [J.M.S.]

10.—Shoemaker calls attention to the danger of spinal injections of cocaine to produce anesthesia, it being a treacherous and unreliable drug, as it often produces most alarming and distressing symptoms when given in small doses hypodermically. The punctures are not easily made and often require 5 or 6 trials. [W.S.N.]

11.—Freer finds the medical treatment of adenoid vegetations of the nasopharynx ineffective and believes the proper method is to remove them with a ring-knife under a general anesthetic, and not in the haphazard method adopted by many. Future deafness and tuberculosis often depend upon the neglect of these lymphoid enlargements in childhood. [W.S.N.]

Domestic Animals in the Causation of Typhoid Fever.—Stokes and Fulton (*Maryland Medical Journal*, November, 1900) as a result of their experiments upon a number of animals, make the following statement: In our experiments we endeavored to produce infection through the natural route and by natural means by simply allowing the various animals to take in very large quantities of typhoid bacilli in their daily food. Although at least 500 colonies from the feces were carefully tested, we were not able to demonstrate the presence of any typhoid bacilli in 3 chickens, 2 white rats, 2 rabbits, 2 guineapigs, 1 calf, and 3 pigs. Although we have not employed a large number of animals, we feel justified in expressing the opinion that the typhoid bacillus cannot, as a rule, maintain its struggle for existence in the intestines of the domestic animals. We therefore conclude that the dejecta of animals play no considerable part in the distribution of typhoid fever. [A.B.C.]

Practical Therapeutics.

Under the charge of

A. A. STEVENS, A.M., M.D.

High Altitudes in Phthisis.—According to Van Pacht (*St. Petersburg med. Woch.* and quoted by the *Medical Review*, October, 1900), high altitudes are contraindicated when there is great anemia. With increasing elevation above sea-level and diminishing atmospheric pressure the blood becomes more concentrated. Whether the increase in the number of red corpuscles contained in a cm. is due simply to this concentration, or whether there is also an increased formation of red blood-corpuscles, is at present uncertain. If the blood is very watery, and then becomes so concentrated that there are as many as 6 to 7 million corpuscles in the cm., the total quantity of blood is reduced to a third or a half of its volume. The patients consequently deteriorate in health. When there is only moderate anemia the concentration of the blood improves nutrition, and is beneficial. The secretion of the lungs and bronchi is diminished, and, therefore, patients with copious expectoration are benefited. With diminished expectoration there is less cough, the lungs are more at rest, and the general condition improves. When, on the other hand, there is dry catarrh, or ulceration of the larynx, the desiccative action of rarefied air tends rather to increase the cough. Such patients do better in a moist climate. In pleurisy, with effusion, the fluid disappears at high altitudes, both by concentration and absorption, more rapidly than in low lying districts. In "dry" pleurisy, however, the deeper or quicker respirations, necessary at high altitudes, act injuriously by increasing the friction between the pleural surfaces. The deeper respiration may cause collapsed portions of the lungs to expand, and often acts in this way more uniformly than is possible in any form of respiratory exercises. But if acute inflammation is present, deeper inspirations may prove a source of danger; the greater pulmonary expansion causes increased movements of the inflamed parts and increases the inflammation. There is also more danger of infectious particles being aspirated into still healthy parts. These are probably the reasons why slight pyrexia often becomes high fever when a patient suddenly exchanges the plains for the mountains; it is, therefore, advisable that patients with pyrexia should travel to high altitudes by slow and easy stages.

Vomiting from Cough in Pulmonary Tuberculosis.—Mathieu (*Rev. de Thérap. Méd. et Chirurg.*, August 1, 1900) makes the following suggestions for the relief of vomiting induced by paroxysms of cough after meals. Small pieces of ice swallowed immediately after the meal often prove successful. In other cases chloroform water with an equal quantity of water to prevent burning of the fauces (4 to 8 drams of the mixture), taken 4 or 5 minutes after meals, will often serve to check the cough. The author, however, has found bromoform water less irritating than chloroform water and recommends a combination of the former with sirup of codein. Menthol is also efficient and may be given in doses of 2 or 3 grains in the form of an emulsion. When all other remedies fail morphin and cocain in equal quantities should be given in distilled water.

The Treatment of Phthisis.—Rea (*Pennsylvania Medical Journal*, 1900) believes that the combination of pulmonary gymnastics with intrapulmonary medication by nebulization under high pressure is a plausible and successful means of fighting this disease. A combination of creasote terebene, oil of eucalyptus, menthol, and a liquid form of petroleum is recommended. This is advocated on account of the belief that such drugs, particularly creasote, used in this manner lessen the fertility of the soil by improving the catarrhal condition. Of all internal remedies that have been advocated, probably creasote has stood the test of time best. It improves appetite, lessens the bronchial inflammation, decreases autoinfection from the bowels, lessens the fever, etc. Recently, however, he has administered ichthyol almost exclusively in place of creasote, and believes it served the same purpose just as well, and yet did not seem to be so irritating to the stomach. Iodoform inunctions as recommended by Flick he has used and believes that they have virtue. The deficient innervation and impaired circulation must also be carefully looked after.

The Intensive Use of Gualacol in Pulmonary Tuberculosis.—Weill and Diamantberger (*British Medical Journal*, October 13, 1900) presented a communication on this subject in the section of Therapeutics at the recent International Congress of Medicine. They claim to have been the first in France to use guaiacol hypodermically. For the last 11 years they have employed the method and they have now a record of more than 500 cases treated and considerably ameliorated by the systematic use of guaiacol. The failures which have been recorded by other practitioners depend on (1) the inferior and variable quality of the liquid, so-called commercial guaiacol. The authors use the synthetic crystallized guaiacol, which may be given in daily doses of 45 and even 60 grains without fear of intoxication; (2) the very small quantity used. The authors use the following formula:

R.—Crystallized guaiacol..... } of each 2½ drams.
Sterilized oil of sweet almonds }
Cocain hydrochlorate 3 grains.

This is mixed with an equal quantity of distilled water and kept in a dark bottle. A daily hypodermic or intramuscular injection of 16 minims is given in the gluteal region. Besides the injections they recommend: Painting the chest-walls with the same solution every night over a space of 8 to 10 square centimeters; enemata of 3 ounces of tepid milk, to which 40 or 50 drops of the same solution have been added; and the following pills (2 every 3 or 4 hours):

—Crystallized guaiacol..... 1 grain.
Crystallized terpin..... 1½ grains.
Benzoic acid..... 2 grains.
Extract of belladonna } of each..... ½ grain.
Extract of hyoscyamus }

To make one pill.

The "intensive and daily guaiacalization," combined with dietetic and hygienic treatment, should be continued for several months, with an interruption of 8 or 10 days every 3 weeks. The symptoms that are most beneficially influenced by the treatment are: expetoration, cough, hemoptysis, fever, night-sweats, diarrhea, and debility.

Cacodylate of Iron in Pulmonary Tuberculosis.

—Sandoz (*Thèse de Paris*, 1900) concludes that cacodylate of iron administered hypodermically is not toxic. When exhibited by the mouth, however, it imparts a garlicky odor to the breath, and produces toxic symptoms owing to its reduction in the intestinal canal. Rectal injections produce effects intermediate between those produced by its administration subcutaneously and by the mouth. In chronic tuberculosis the cacodylate of iron usually causes rapid improvement in the appetite, an increase in the body-weight, a disappearance of the night-sweats, a lowering of temperature, and an amelioration of the general condition. The dose for hypodermic use is ½ to 1½ grains.

Diarrhea of Phthisis.—Nestor Tirard (*Medical Treatment of Diseases and Symptoms*, 1900): I have for a long time been in the habit of giving alum for the control of the diarrhea of phthisis, and I give it in 5-grain doses, repeated 3 or 4 times during the day, increasing the dose little by little, if the symptom continues in spite of this treatment. When the diarrhea is dependent upon enteritis, alum is frequently of great service, and even in cases associated with ulceration, the number of actions daily is often reduced during its employment. As a rule, this remedy is well tolerated, provided its administration is commenced gradually, and the dose increased only as toleration is established; but I have known it to produce vomiting and nausea when used for children in injudiciously large doses. Other astringents are often used, as, for example, copper sulfate, which may be given in doses of ½ to 2 grains in pill. Lead acetate is also frequently of service in this condition, and can be given in the pill of lead and opium. Logwood is often used, and it may be given with the chalk-mixture of the pharmacopeia. The effect of these remedies is often increased by the simultaneous administration of some form of stimulant. In children I have often seen diarrhea arrested by the mistura vini Gallici of the British Pharmacopeia, which also appears to counteract the exhaustion which so commonly results from this symptom. The composition of this mixture is as follows:

R.—Brandy 4 ounces.
Cinnamon water..... 4 ounces.
Refined sugar..... ½ ounce.
Two yolks of eggs

Food in Tuberculosis.—Mitchell Bruce (*Treatment in Practical Medicine*, 1900) writes: "When anorexia, discomfort, vomiting, and the other evidences of indigestion, such as depression, languor, headache, constipation and turbid urine, make their appearance in phthisis, they are too often directly referred to the tuberculosis or to the fever. The patient is ordered milk, essences, and every description of patented and advertised foods and 'wines;' oil, tonics, malt, and the latest specific for tuberculosis are given even more freely than before. The exercise of a little common sense ought to have prevented all this. The first step to take in such a case is to prescribe a mercurial purge, followed by a saline. The second step is to order a diet of light solids, and specially to supervise the breakfast and supper menus, and to cut off stimulants and all manufactured materials, excepting a good peptonized cereal food at the evening meal. Thirdly, the times and manner of taking food must be revised. Excessive frequency and excessive amount must be temporarily avoided. If sickness be prominent and persistent, bodily rest is indicated; and the patient should lie down for half an hour before his mid day meal and for at least two hours after it. Sometimes, indeed, obstinate cough and vomiting have to be met by confining the patient to a couch and bringing him his meals, which he takes in the reclining posture. Counterirritation is often successful in the distressing cases where feeding provokes paroxysmal cough, ending in vomiting and loss of the entire meal, a fly-blister to the epigastrium, application to the pharynx or larynx, and iodine paint over a large secreting cavity are different measures called for different conditions. The best internal remedy is a combination of sodium bicarbonate, sal volatile, diluted prussic acid, and diluted infusion of a vegetable bitter stomachic, given shortly before meals to relieve the mucous catarrh of the stomach and to promote the appetite and secretion of gastric juice. Night feeding in active phthisis is indicated by several conditions: that the night is too long for a patient with advancing tuberculosis to go unfed, patients with pneumonia being fed every two hours; and that broken sleep produces restlessness, increase of cough, sweats and exhaustion."

The Value of Antiseptic Nebulæ in Pulmonary Tuberculosis.

—Thomas (*Chicago Medical Recorder*, October, 1900) draws attention to the value of antiseptic nebulæ—formalin (6%), eucalyptol, oil of cinnamon, etc.,—in the treatment of pulmonary tuberculosis, and draws the following conclusions: 1. The respiratory capacity, so limited in tuberculous patients, is increased. 2. The catarrhal condition of the air-passages is diminished, thereby aiding a better introduction of air into the lungs. 3. The pulmonary passages are kept in an aseptic condition and the danger of new bacillary invasion minimized. 4. The marked relief of cough and dyspnea. 5. The alimentary tract is undisturbed by drugs, giving ample opportunity for the increase of vital resistance by suitable diet and constitutional treatment.

Prophylaxis against Tuberculosis.—Abbott (*Hygiene of Transmissible Diseases*, 1899), after dealing with the treatment of sputa, and recommending the paper "Japanese handkerchief" for use when the patient is away from his apartments, continues as follows: "Bed-clothing or night-clothing soiled with tuberculous sputum should be at once removed and scalded. The consumptive should be provided with his own eating utensils, napkins, etc., and these should be used by him alone, and should be scalded immediately after use. The refuse from his meals should also be scalded, never used by others. The living- and the bed-room of the patient should be kept scrupulously clean, and should be frequently aired. Under no circumstance should spitting about the room be permitted. 'Dusting' should not be practised, but when necessary all objects should be wiped with a cloth moistened in 1 to 1000 corrosive sublimate or 3% carbolic acid solution. The importance of this precaution is conspicuously illustrated in Cornet's investigations by the marked difference between the dusts from medical wards of hospitals, where there is more or less laxity concerning the importance of cleanliness as a factor in sepsis, and the dusts from surgical wards, where this point is kept constantly in mind. Kissing, caressing, shaking hands, and other modes of intimate association should not be indulged in by the consumptive. The hands should be thoroughly washed after manipulating tuberculous patients."

THE REGISTRATION OF TUBERCULOSIS.¹

By HERMANN M. BIGGS, M.D.

of New York.

Pathologist and Director of the Bacteriological Laboratories, Department of Health, New York City; Professor of Therapeutics and Clinical Medicine, and Adjunct Professor of the Practice of Medicine, University and Bellevue Hospital Medical College.

I DESIRE to express my sincere appreciation of the honor conferred by the invitation tendered by the trustees of the Philadelphia County Medical Society to address the Society on "The Registration of Tuberculosis," and for this I wish to render my grateful acknowledgment. I have accepted the invitation more readily because for many years I have been greatly interested in the sanitary surveillance of tuberculosis, and it has been my great privilege to assist somewhat in advancing the measures adopted by the Department of Health of New York City in dealing with this disease.

There is no problem which confronts the sanitary authorities of the large municipalities at the present time exceeding in its importance and magnitude that presented by the tuberculous diseases, nor is there any other sanitary proposal which offers promise of such large returns in a diminishing morbidity and mortality-rate as one which provides successful measures for the prevention of tuberculosis.

This is not a new problem. The tuberculous diseases are not more prevalent than formerly; on the contrary, there has been a steady and very material decline in the death-rate caused by them; but only in recent years have the sanitary authorities and the medical profession begun to have some realization of the great possibilities in the way of the restriction of this disease. A comprehension of the full meaning of the discovery of Koch on the prevention of tuberculosis has very slowly found its way into the minds of the medical profession, and even now after 18 years a large proportion of the profession have not grasped its vast significance on the future happiness and prosperity of the human race. Statistics showing the great prevalence of this disease have been quoted frequently enough to have almost lost their meaning, and the people, the legislators, the sanitary authorities and even the medical profession have become indifferent to the vast expenditure in suffering and death unnecessarily paid by the human race to this evil. Only limited and ineffectual efforts are being made in its suppression. We still view with comparative indifference the ravages of a disease which causes from $\frac{1}{4}$ to $\frac{1}{3}$ of the suffering and death at the best period of life—15 to 65—and this, too, when the evidence at command should be, it seems to me, conclusive to every reasonable mind, that it can be largely prevented at a comparatively small cost in sacrifice, labor and money. I make this statement with a full realization of its meaning, and after a familiarity with the sanitary problems involved, gained by an active participation in their study in a great city for a period of more than 12 years.

In 1888, through my intercession, the Board of Health of New York City passed a resolution asking for a report from the consulting pathologist on the causation and prevention of tuberculosis. I would add today but one measure to those advocated at that time, namely

the compulsory notification of this disease. But unfortunately the position recommended then was not reached by sanitary achievement until 10 years later.

The practical difficulties in the way of the notification of tuberculosis are undoubtedly considerable and sanitary authorities generally in Europe with characteristic conservatism have pronounced against it. Sir Richard Thorne, medical officer to the local Government Board of Great Britain, in the Harben lectures, 1898, on "The Administrative Control of Tuberculosis," after a careful consideration of the various problems presented under the English law relating to infectious diseases, pronounces definitely against it, on the ground that the hardships to the individual which would follow notification and the enforcement of proper regulations would be so great as to render this measure unjustifiable.

He says: "The justification for the demand that phthisis shall be compulsorily notified lies in the fact that the person in question is suffering from a dangerous infectious disease, communicable from person to person; hence the question is already arising, whether it is right to allow such a person to be in constant association with hitherto healthy people by day, and still more so by night. It is quite certain that the need for adopting special precautions as to the sputa, etc., would lead to a large number of such persons being quietly dismissed from their posts. If such persons need fresh employment they will certainly take care to avoid directing attention to their malady by the adoption of the precautions urged on them by the interests of the public, and it is equally certain that they would to the utmost avoid consulting another medical practitioner, because their disease would again be known and the same consequences that followed the first notification might again be brought about. Without following out such cases as these for several years and to the bitter end, it will suffice for me to say (adds Thorne) that in my opinion a large amount of harm would result if phthisis were included in the list of notifiable diseases under the English act. The certain knowledge that notification and the intervention of public officers would ensue would prevent resort to medical advice in the early stages of the disease when its progress can best be arrested."

He says: "I believe that the attempt on the part of the phthisical persons to avoid notification would in itself do a great amount of harm, not only to the individuals already suffering, but to the healthy with whom they are in daily association. The English law as to the compulsory notification of contagious diseases was never intended to bring under a system of public supervision even a single individual, who during a long series of years would have to follow his or her usual avocation. This supervision might in a majority of cases be carried out with every discretion and every effort to avoid publicity, but if it were carried out under the present system of sanitary organization or under the present law it could not but run the risk of leading to hardship beyond that which the public has a right to expect others to suffer on their behalf, and indirectly this would, in the end, defeat the primary object held in view."

It may be said in reply to this, that there are several implied assumptions, which do not appear to be justified by the facts. In the first place, it is assumed that notification will give a publicity which did not previously exist. This assumption is certainly untrue, under the

¹ Read before the Philadelphia County Medical Society, November 14, 1900.

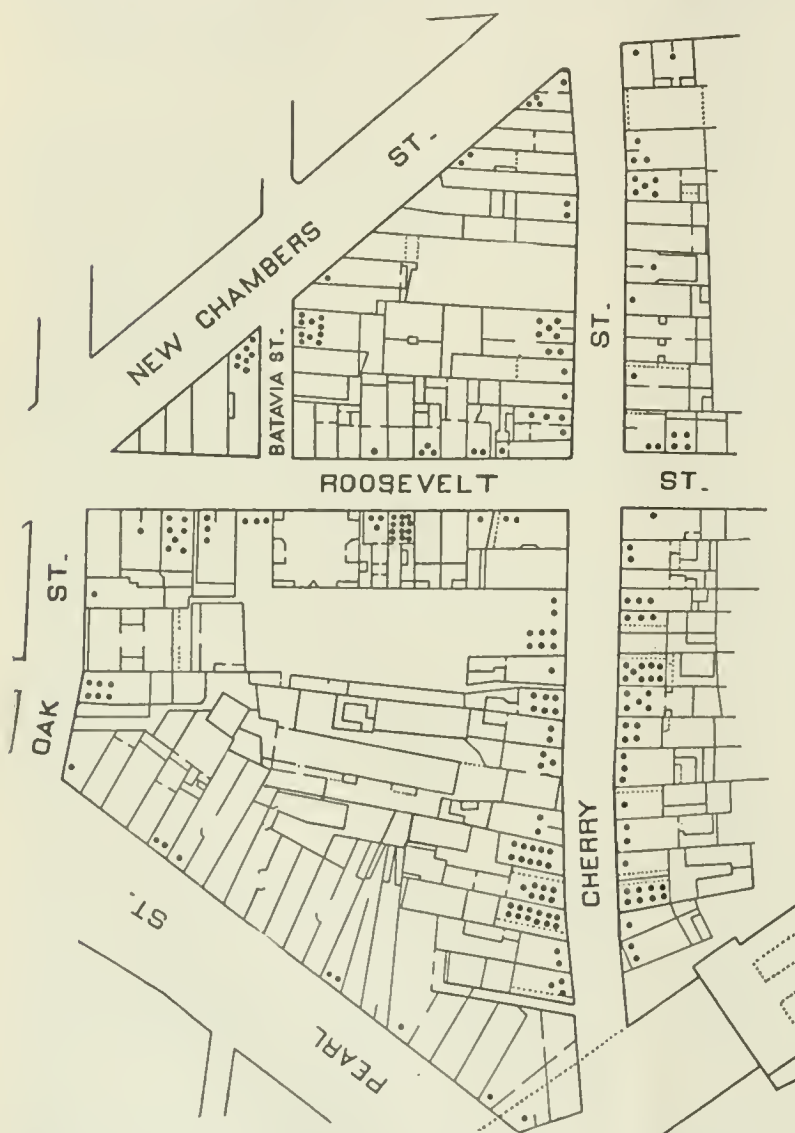

regulations adopted by the Department of Health of New York. There is no reason why notification, followed by suitable instructions to the patients, should involve such publicity. In the second place, with the increasing knowledge of the nature of tuberculosis among the laity, it is unreasonable to believe that a person suffering with cough and expectoration and showing the ordinary signs of advancing tuberculous disease would not be recognized by his associates as a consumptive, and he might, therefore, under any conditions be subjected to the same hardships which Thorne feels must necessarily follow notification. On the other hand,

symptoms as of no consequence and to postpone from week to week and month to month consulting a medical adviser, because they believe the disease is of little importance. It is incomprehensible to me how a sanitary officer can assume the position that a tuberculous patient should be left in a general workroom carelessly disposing of his expectoration and thus exposing large numbers of others to possible infection, because it is believed that the observance of proper sanitary precautions in regard to the expectoration will be followed by a recognition on the part of his fellow workmen and his employer of the tuberculous nature of his affection and this may result in his dismissal. This is in substance an encouragement to consumptives to neglect the required sanitary precautions, in order that no suspicion may arise as to the nature of their disease; and it involves the exposure of considerable numbers of persons, for several years perhaps, to tuberculous infection, in order that the dreaded day may be somewhat postponed for the individual. This attitude on the part of the consumptive, and the participation in it on the part of the medical adviser, to say nothing of the sanitary authorities, seems to me most reprehensible.

I believe that measures differing essentially in their nature from those which are observed in the contagious diseases should be observed in relation to tuberculosis. The facts do not warrant our classing tuberculosis with smallpox, measles, diphtheria, and scarlet fever. It is a dangerous, infectious, communicable disease, but differs in many important particulars from these highly contagious affections. But the fact that the disease requires different treatment from the contagious affections does not justify us in neglecting those things which are obviously necessary for the protection of the public health. If the sanitary authorities in England or elsewhere have not the power under the present statutes to place tuberculosis in a separate class as Thorne seems to intimate and to deal with it in a different and proper way, then certainly some attempt should be made to obtain such power through legislation. In New York State no such additional power is required, and I doubt whether it is in any one of the United States. It should be said, however, that some of the municipal sanitary authorities of Great Britain have asked for power from the local government board to institute special measures in relation to tuberculosis, and in several cities, as Manchester and Brighton, a system of voluntary notification, with measures for inspection, disinfection, etc., have been adopted; and many of

the municipal sanitary authorities of Great Britain have urgently besought the local government board to place tuberculosis in the class of notifiable diseases.

It should be said that in France also the attitude of the medical profession towards tuberculosis is much the same as that in Great Britain. A special commission of the Academy of Medicine in Paris in May, 1898, reported against such a procedure. Two principal reasons were advanced against the proposition; the first points

Reproduced from the sectional maps of New York City on which are plotted the reported cases and deaths from pulmonary tuberculosis from the beginning of the work in 1894 to January 1, 1899. Each case reported and each death is indicated by a dot (duplicates excluded). The lots in which no dots are seen are chiefly warehouses, and are not occupied at all as dwellings.

as the knowledge of the exact nature of tuberculosis becomes thoroughly disseminated among the people, they would soon understand that a consumptive who habitually disposes of his sputum with care is not a source of danger. The contention of Thorne, that these patients would recognize early the nature of their disease and avoid medical advice is unreasonable, because the experience of every practitioner is that the tendency of consumptives is always to regard the cough and

out that notification involves the divulging of a medical secret which would be harmful to the patient (this also equally applies to the contagious diseases), and insists that as the public does not regard tuberculosis as in the class with diphtheria or smallpox, and as it is considered by them as hereditary, the public would not accept such a legal enactment without protest and resistance. The second is regarded as more important, and is that in a family unwilling to follow instructions, restrictions would be impossible, as they would necessitate an almost continuous intervention on the part of the sanitary officers for months and years. The only efficient alternative in such cases, it is pointed out, would be the consignment of the consumptive to a hospital—a practice followed in Norway. This, it seems to me, is the proper course. The commission concludes that compulsory notification must not be dreamt of—at least immediately.

In considering the advisability or the sanitary necessity for the compulsory notification of tuberculosis, certain facts in relation to the disease, perfectly well known and much insisted on in all recent writings on this subject, must be repeated. These may be placed seriatim as follows:

1. Tuberculosis is an infectious and communicable disease produced by the tubercle-bacillus.

2. There is no satisfactory proof that the tubercle-bacillus multiplies outside of the living body under natural conditions; it follows as a necessary sequence that every case of tuberculosis is produced by the reception of the same *identical tubercle-bacilli* which have been thrown off by some other human being or by some animal suffering with tuberculosis.

3. The tubercle-bacilli producing an infection are generally obtained from dust contained in the air breathed, or in the drink or food taken.

4. The tubercle-bacilli thrown off by a person or animal suffering from the disease are contained solely in the discharges from the tuberculous tissues, and it should be possible to absolutely control their dissemination.

5. It follows therefore that tuberculosis is preventable, and (in the early stages) clinical experience shows that it is curable.

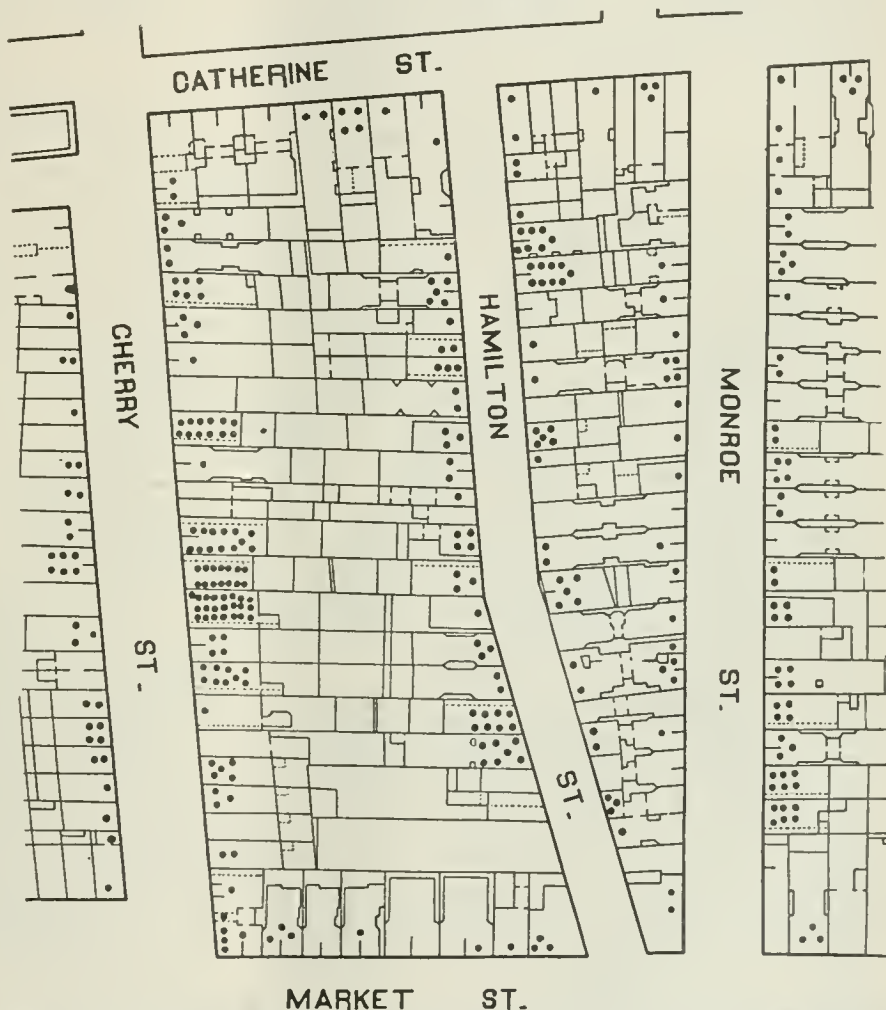

6. It is by far the most fatal disease with which we have to deal, and from both an economic and sanitary standpoint is of vastly greater importance than any other infectious disease, both because of the number of deaths it causes, and the suffering it produces. Its importance is further enhanced because it occurs to the greatest extent in the working period of life, and its victims are cut off at the time of their greatest usefulness.

7. Its prevention requires the exercise of enlightened cleanliness on the part of its victims, which presupposes education, suitable hospital accommodations for the care of advanced cases among the poor, and the efficient disinfection of dwellings.

These ends can no more be attained in tuberculosis without registration than they can be in the contagious diseases.

It seems to me that compulsory notification is a necessary preliminary to other measures and that little further advance can be made without it, or at most the advance must be exceedingly slow.

I believe that the arguments which have been urged

Reproduced from the sectional maps of New York City on which are plotted the reported cases and deaths from pulmonary tuberculosis from the beginning of the work in 1854 to January 1, 1899. Each case reported and each death is indicated by a dot (duplicates excluded). The lots in which no dots are seen are chiefly warehouses, and are not occupied at all as dwellings.

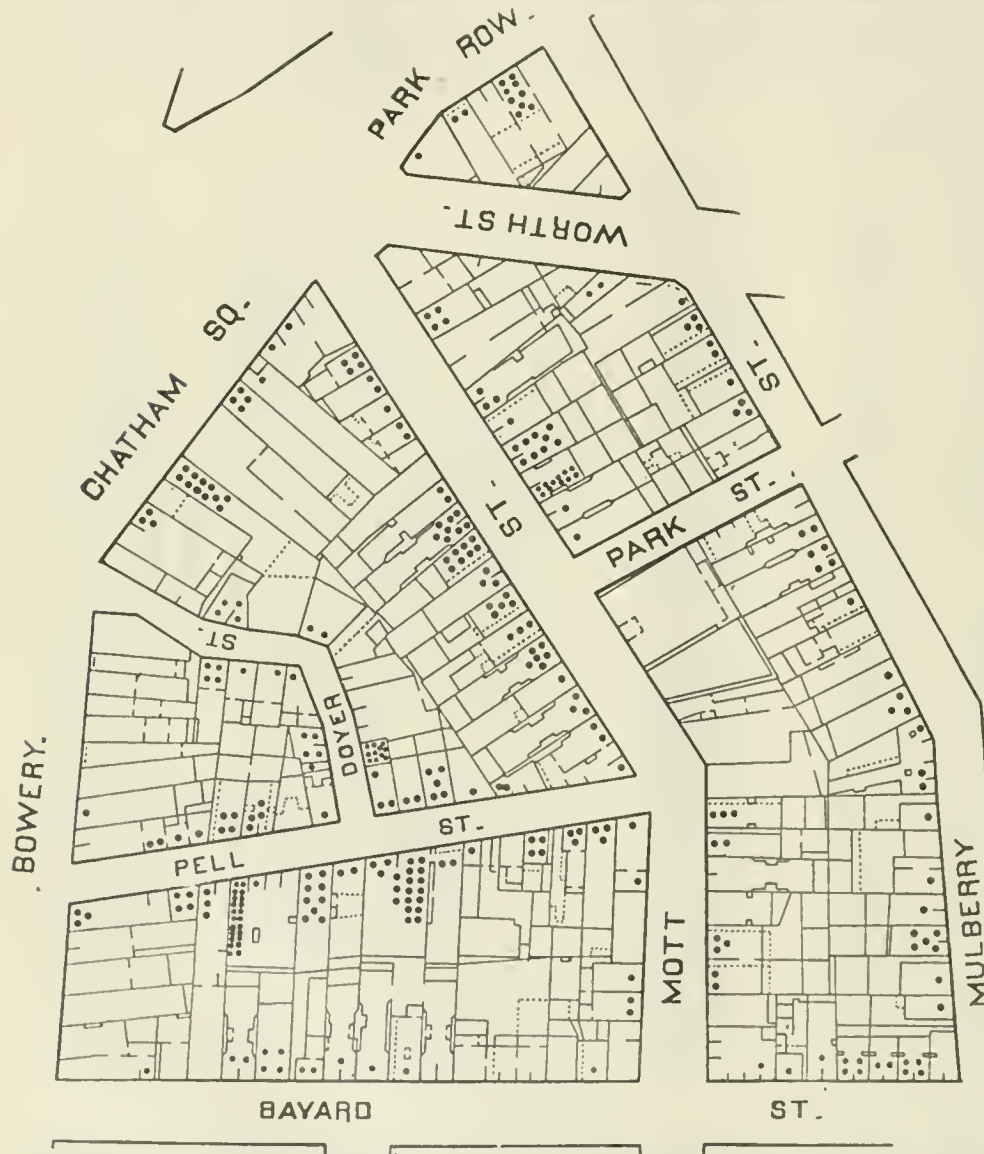

against compulsory notification are usually based on improper or erroneous conceptions, and are not valid objections to the adoption of this measure.

It has been urged against it:

1. That the disease is not highly contagious, as are those diseases in which notification is required; that it is not of limited duration, and that long and constant exposure is required to produce infection. It may be said in reply, simply, that the evidence is conclusive, that tuberculosis is produced by the tubercle-bacillus and that every case is the result of infection by the same tubercle-bacilli, which have been thrown off by some other being suffering from tuberculosis. I cannot see

that any other answer is required, for it matters not how indirect the infection is, or how difficult it may be to trace it, or how slow and insidious may be its development, or how prolonged the exposure required, the one fact remains that tuberculosis is the result of such infection, and if the arguments quoted have any effect it is to emphasize the importance of the adoption of proper sanitary measures, including registration, because the disease on account of these peculiarities is far more easily

sources of infection will not produce more cases than 500; no one will insist that sanitary precautions are useless and are to be abandoned because they are not absolutely reliable, and because they are simply means by which we diminish to a greater or less degree the chances; all sanitary measures are subject to limitations in greater or less degree; and so in tuberculosis, while no one would assume that in a single month or in a single year all of the thousands and tens of thousands of sources of

Reproduced from the sectional maps of New York City on which are plotted the reported cases and deaths from pulmonary tuberculosis from the beginning of the work in 1894 to January 1, 1899. prevented than the purely contagious affections.

2. It has been urged that tuberculosis is so widely distributed—"so ubiquitous"—that any attempt at its prevention by the means advocated should not be considered. This argument again is one of the strongest seasons which could be urged for action. The proposition that any attempt to cope with this question should be abandoned because the problem is so large is certainly not worthy of consideration. It surely cannot be seriously urged that we shall give up active preventive measures because an immediate completely successful result cannot be obtained. No one will maintain that a 1,000

infection in a great city can be removed, yet if one-quarter or one-third can be eradicated there will be a proportionate gain, which will be increased each succeeding year. To individualize still more, it is certain that if an advanced case of pulmonary tuberculosis is taken away from his family in a tenement house, or is taught to carefully destroy his sputum, the chances of the infection of members of the family or of the inmates of the house will be diminished, and with each source of infection thus removed a definite gain will surely follow.

3. It has been strongly urged that in many instances it is undesirable that the patient should know that he is the subject of tuberculosis, and that this knowledge will affect his well being.

This view, although earnestly held by many physicians, I believe is usually erroneous. In a considerable experience in dealing with consumptives during the last 15 years, I have become convinced that by far the best course to pursue in most cases when an individual is found to be suffering from tuberculosis is to frankly inform him of the fact. The information may be a shock and a source of mental suffering and anxiety, but the ultimate effect will, I believe, be in the patient's interest, for the patient will then observe the precautions which

are required for his own recovery and for the prevention of infection in others and reinfection in himself. He will further consent to the adoption of such radical changes in his life and work, if these be possible, as are necessary for increasing his chances of recovery. I believe that the actual knowledge of the condition existing is less harmful than the apprehension and dread which these patients often have before they possess the knowledge. How frequently have I heard patients complain most bitterly of their physicians, for not having informed them of the nature of their disease. In any event it certainly will not be maintained that to

save the individual some suffering, it is justifiable that all who come in contact with him for months or for a period of years should be exposed to the danger of infection. It surely will not be maintained that the possibility of bringing suffering, disease and death to many others, to say nothing of the danger of self-reinfection, is a lesser evil than the possibility of causing some temporary suffering to the individual. Further than this, if the disease is in a curable stage this knowledge increases the chances of recovery; (if it is in an incurable stage, then at most it renders a few months of the individual's life a little less happy than they might otherwise have been). One of the fixed principles in the organization of society is that, if necessary, the welfare of the individual must be sacrificed to the welfare of the community.

4. It is urged that if it becomes known that an individual has tuberculosis, he will become socially ostracized. In reply it may be said that this statement is greatly exaggerated. Already, with the increase in popular knowledge in regard to the nature of tuberculosis, the unreasoning dread of the disease which existed at first is disappearing and is being replaced by a more intelligent conception of its nature and the means for its prevention. It cannot be too strongly insisted that, with the observation of proper precautions a tuberculous patient may be absolutely free of danger to his intimate associates. When the knowledge of this fact has become firmly fixed in the minds of the community a great advance will have been made.

5. It is urged that the disease is of long duration; that the individual may be able to carry on his usual avocation for a long period of time, and that the knowledge that he has tuberculosis may result in his being deprived of employment, or may render it impossible for him to find a suitable home.

In reply to this it may be said that too much importance is given to these latter statements; first, because notification to the sanitary authorities does not involve notification to the community at large; second, because in most occupations if the individual observes proper precautions he does not become a source of danger.

Even if all were true which is urged, certainly these considerations would not justify the continuous exposure to infection of large numbers of persons, with the moral certainty that some would contract the disease, in order that one individual might be able to pursue for a few months or a year or two longer his usual occupation.

6. It is urged that the medical profession and the community are not yet ready to accept such advanced measures, and that it is useless to attempt to enforce such measures without their support.

In reply to this it may be said that experience has shown that the people as a whole and even most consumptives will and do support this measure, and that the fact of notification in itself is in the first instance of great educational value. In no way can we impress so strongly on both the profession and the people the communicability of this disease. No reasonable sanitary officer would expect to put into force regulations requiring the notification of tuberculosis, with the same conditions and in the same way, that a similar one in regard to smallpox would be enforced. The process of the enforcement of such a law must be developmental, and it must be distinctly understood and strongly and constantly emphasized, that tuberculosis is a different kind of disease from smallpox or scarlet fever or any of

the other highly contagious affections. It should be placed in a different class, and I strongly deprecate the practice of calling it contagious. In New York City the amendment to the Sanitary Code requiring notification declares tuberculosis to be a communicable disease (not a contagious one), and it is stated explicitly in the circulars of information, that it differs in many and important essentials from those diseases commonly known as contagious. The notification must be within one week of the time that the patient comes under observation. In adopting the system of notification, it was first applied by a resolution of the board solely to public institutions, hospitals, dispensaries, etc., those dealing chiefly with the tenement-house population. After this resolution had been in force for nearly three years it was replaced by an ordinance, and its scope extended to include also cases occurring in private practice.

The ordinance adopted in New York City in 1897 reads as follows:

"Resolved, That pulmonary tuberculosis is hereby declared to be an infectious and communicable disease, dangerous to the public health. It shall be the duty of every physician in this city to report to the Sanitary Bureau in writing the name, age, sex, occupation, and address of every person having such disease who has been attended by or who has come under the observation of such physician for the first time, within one week of such time. It shall also be the duty of the commissioners or managers, or the principal, superintendent, or physician of each and every public or private institution or dispensary in this city to report to the Sanitary Bureau in writing, or to cause such report to be made by some proper and competent person, the name, age, sex, occupation, and last address of every person afflicted with this disease, who is in their care or who has come under their observation, within one week of such time. It shall be the duty of every person sick with this disease, and of every person in attendance upon anyone sick with this disease, and of the authorities of public and private institutions or dispensaries to observe and enforce all the sanitary rules and regulations of the Board of Health for preventing the spread of pulmonary tuberculosis."

I may say that when this ordinance was adopted every important medical society in New York City protested against the action of the Department of Health, but these protests showed by their wording and the remarks which accompanied them, that the protestants did not understand the scope of the action of the Department of Health, and that they had arisen in protest against an imaginary evil. They protested against tuberculosis being called a contagious disease, but the Department of Health never called tuberculosis a contagious disease, and expressly stated that it was communicable and infectious, but not contagious. A determined, but unsuccessful effort was made by the New York County Medical Society to obtain legislation which would deprive the Department of Health of the power to deal with tuberculosis.

There have been few protests, however, during the last two years against the action or attitude of the Department; there has been acquiescence, and apparently approval, and it is certainly true that the action of the Department has been followed by greatly increased interest and knowledge regarding tuberculosis, and by the institution of active measures in the State and in the city looking towards its care and its prevention.

It is true that the Department of Health has not endeavored to enforce strictly the regulations. It was not the intention to do so when they were enacted. It has not prosecuted physicians who have failed to report cases; the Board is well aware of the fact that large

numbers of cases are not reported; but still a constant advance in the right direction is being made. The attention of physicians who report deaths due to tuberculosis in cases which have not been previously notified is now called by special letter to the provision of the sanitary code requiring the reporting of such cases, and they are asked for an explanation for the failure to report the case. The superintendents of public institutions are constantly reminded of their obligations in this matter, and usually twice a year a census is made of all the cases under care in all the public institutions in the city. About 9,000 new cases (duplicates excluded) are reported annually, and these as well as the premises where 9,000 deaths occur are inspected. It is the purpose of the Board of Health to ask for a special additional appropriation for the coming year to extend and perfect the work now being done.

No method can be devised, so far as I can see, which will give the required information to the sanitary authorities regarding the cases of tuberculosis in tenement houses, lodging houses, hotels, boarding houses, etc., excepting a system of compulsory notification. It would be undemocratic, and probably illegal, to require the reporting of cases living under certain conditions, as in tenements, and to exclude those living under other conditions, as in private houses, but the sanitary authorities may use their discretion in regard to the measures which shall be adopted under varying conditions, depending upon the danger which they conceive exists as far as the public is concerned. As a matter of fact, in private houses, and in cases reported by private physicians, no action is taken, excepting as to registration; this position is assumed and conditioned upon the medical attendant giving such information as is necessary to the patient in regard to the means for the prevention of the disease. The fact that the physician reports the case is regarded as constituting proof of his realization of the communicability.

A large number of cases are reported through the examinations of sputum; and a curious feature presented in this is that physicians, who strongly object to reporting cases of tuberculosis, will send specimens of sputum for examination, with the data which constitute a report. About 2,500 cases from private practice will be reported the present year through the sputum examinations.

It does not seem to me that there has been one single valid objection advanced to a rational system of notification of tuberculosis. There is no reason why every disease in which notification is required should be placed in the same class. Tuberculosis should be declared to be an infectious and communicable disease and treated alone, or in a class including typhoid fever, and perhaps some other diseases.

In order that cases of tuberculosis shall be properly dealt with it is necessary that the sanitary supervision in every municipality shall comprise: 1. Compulsory notification. 2. Suitable plans for the education of the people, including the visiting and instruction of cases, especially those residing in tenement houses, lodging houses, boarding houses and hotels (I would not include in this measure persons living in their own houses). 3. A complete and efficient scheme for the disinfection or renovation of premises vacated by death or removal. 4. A hospital equipment, consisting of a reception pavilion for tuberculous patients, a suitable institution within or near the municipal limits, for the care of advanced cases, and a country sanatorium in a well-situated locality for the care of incipient cases. 5. The

power of compulsory removal and retention of patients in a hospital when necessary, in the same manner as is practised in the contagious diseases. In only rare instances would the exercise of this power be required, but occasions sometimes present themselves in which such action is necessary. The following is one of a number of instances which have come under my observation:

The owner of a sweat-shop in a tenement-house district was found to be suffering from advanced pulmonary tuberculosis. He employed in his workrooms, which were close and badly ventilated, a considerable number of young women. He was excessively filthy in his habits and refused to follow directions given in regard to the care of his expectoration, and he persisted in spitting on the floor, wall, or anywhere that was convenient. I should unhesitatingly favor the forcible removal of such a patient by the sanitary authorities. It may be said, however, that if the power for forcible removal was possessed by the authorities it would rarely be necessary to exercise it.

Let us consider for a moment, what registration has already shown in New York as to the nature and the extent of the problem with which we have to deal. At the beginning of this work in New York City in 1894, I had prepared sectional maps of the city, showing every house-lot in the boroughs of Manhattan and the Bronx, on a scale large enough so that reported cases and deaths could be plotted in each house-lot by conventional signs, which indicate the month and the year of the report. From these maps I have selected a few blocks in which the largest number of cases have occurred, and had them reproduced. On these maps each case reported is indicated by a dot. These show that on a single street-block as many as 102 cases have been reported within a period of 4½ years, and as many as 24 cases in a single house. For example, on the block on Cherry Street between Pearl and Roosevelt, 102 cases have come to the notice of the department from April, 1894, when this work was begun, to January 1, 1899. The population of this block in January, 1900, as enumerated by the sanitary police of the Department of Health, was 1,165. On another block bounded by Cherry, Market, Catherine and Monroe streets, there were 241 cases of tuberculosis, with a population of 3,688. In a third one, which includes particularly the Chinese quarter, bounded by Chatham, Mott, Bayard Street and the Bowery, there were 206 cases, with a population of 2,102. These districts represent perhaps the worst conditions existing in the city, but the number of cases in many others nearly approximates the number found in these. And throughout the tenement-house districts everywhere large numbers of cases have been reported. I presume we must add to these numbers at least one-half more and perhaps nearly two-thirds as many more to cover the unreported cases, for I do not believe more than two-thirds of the cases in Manhattan and the Bronx are now reported.

With a problem of such magnitude as is here presented, how are the authorities to obtain information in regard to the cases without compulsory notification? and without knowledge, how can they hope to deal with any measure of success with the existing conditions? I have never heard those who object to registration suggest any practical alternative, and I believe there is none to be found. It may be said that such conditions as have been described do not exist in this country outside of New York City. Perhaps this is in a measure true; but no one can foresee what will be found in any

city until the cases are registered, and I have no doubt that conditions approximating those present in New York City would be found in every large city.

It may be asked, When cases are registered, what sanitary measures should be proposed for the prevention of the disease? In reply I would say:

1. The inspection of the premises in tenement-houses, lodging-houses, hotels, boarding-houses, etc., and the personal instruction of the consumptives by medical inspectors as to the necessary precautions, and the furnishing of proper circulars of information in regard to the disease and the method of its extension.

2. The disinfection or renovation of all premises vacated by the death or removal of consumptives, and, when required and practicable, the employment of the same measures during life.

3. The removal (so far as it is possible, to provide hospital accommodations) of all advanced cases, who are unable to work and who will consent to enter a hospital.

4. The provision of accommodations in country sanatoriums for incipient cases.

5. The supervision of shops, occupations, and conditions, where consumptives are employed.

6. The forcible removal, in those rare instances, in which consumptives are unwilling or unable because of weakness, to observe required precautions, and where such removal is deemed necessary, because of the unusual exposure to which others are subjected.

Shall we allow tradition, prejudice and sentiment to longer delay the solution of this the most important, as judged from every standpoint, of all the sanitary problems of the time? If opposition there be, it is largely in the medical profession, for our experience in New York has shown that the people in general and the lay press will warmly support all measures designed for the prevention of this disease. As to the final adoption of compulsory notification, I think there can be no question. It only remains to be decided whether the 18 years which have elapsed since Koch's discovery have sufficed to educate and convince the profession, for it is from them that the initiative must come.

There has been a reduction in the mortality from the tuberculous diseases in New York City since 1886 of more than 35%, and I have no hesitation in saying in conclusion that I believe, with a complete and efficient scheme for dealing with pulmonary tuberculosis, including suitable hospital accommodations and the proper enforcement of precautionary measures, the death-rate from the tuberculous diseases in New York City may be further reduced $\frac{1}{3}$ within a period of 5 years. This would mean the saving of 3,000 lives annually. Notification seems to me a logical necessity and a necessary preliminary to the adoption of other sanitary means for the prevention of this disease.

ON THE STUDY OF TUBERCULOSIS.*

By WILLIAM OSLER, M.D.,

of Baltimore, Md.

THE history of the acceptance of any great truth in medicine is an interesting study. A slow, gradual recognition seems essential to permanency and stability. As Locke well said, "Truth scarce ever yet carried it by vote anywhere at its first appearance." Even in this

electric age the practical application of new knowledge is singularly tardy. Antiseptic surgery took twenty years to win its victory, and for about the same period we physicians have been participants in another long warfare, the successful outcome of which may be said to be now in sight. The twentieth anniversary of the discovery of the germ of tuberculosis by Robert Koch is near at hand—a discovery which, in far-reaching results, will prove to have had few equals in human history. Since 1881 the laboratory phase of the question, with its experiments and researches, has so far been the most complete; the clinical side has been enriched with two facts of supreme importance; first, the earlier and more positive diagnosis of the disease; and, second, a fuller knowledge of the means for its cure; and we have now entered upon an economic stage, and the tuberculous leagues and congresses, laws and enactments, show how alive we have become to the importance of the disease in national and civic life.

I. *General Relations of Tuberculosis.*—If we compare the mortality bills of any large city today with those of fifty years ago, the most striking change is in a reduction of the deaths from fever, and in the absence of the names of certain diseases which were formerly amongst the most fatal of their kind. Public hygiene has done a great work in ridding us of several of the great scourges, and in lessening the danger from such epidemics as cholera and yellow fever. Of the 10,152 persons who died last year in this city, 3,765 were victims of the infectious diseases. Measles, scarlet fever, diphtheria, whooping-cough, influenza and dysentery together accounted for 801. Three diseases head the list, each one as fatal as all the others combined; tuberculosis of the lungs 974, pneumonia 778, and cholera infantum 703. If we add the deaths due to tuberculosis of other organs, we are well within the mark in saying that one-tenth of the deaths in this city are due to this disease. It is estimated that above a million of persons are suffering with consumption alone in this country, of whom at least 150,000 die annually. The white plague, as Holmes called it, is the great scourge of the race, killing more than 5,000,000 yearly. Let me read you an abstract from De Quincey, which, while expressing an old, erroneous idea, gives in his strong and characteristic language the terrible, the appalling nature of this annual slaughter. "Are you aware, reader, what it is that constitutes the scourge (physically speaking) of Great Britain and Ireland? All readers, who direct any part of their attention to medical subjects, must know that it is pulmonary consumption. If you walk through a forest at certain seasons, you will see what is called a *blaze* of white paint upon a certain *élite* of the trees marked out by the forester as ripe for the axe. Such a blaze, if the shadowy world could reveal its futurities, would be seen everywhere distributing its secret badges of cognizance amongst our youthful men and women. Of those that, in the expression of Pericles, constitute the vernal section of our population, what a multitudinous crowd would be seen to wear upon their foreheads the same sad ghastly blaze, or some equivalent symbol of dedication to an early grave. How appalling in its amount is this annual slaughter amongst those that should by birthright be specially the children of hope, and levied impartially from every rank of society! Is the income-tax or the poor-rate, faithful as each is to its regulating tide-tables, paid by any class with as much punctuality as this premature *florilegium*, this gathering and rendering up of blighted blos-

* Introductory Remarks at the organization of a Society for the Study of Tuberculosis, Johns Hopkins Hospital, October 30, 1900.

soms by *all* classes? Then comes the startling question—that pierces the breaking hearts of so many thousand afflicted relatives—Is there no remedy? Is there no palliation of the evil?" Let us be thankful that we can answer today—There is!

II. *Some Special Features of Tuberculosis as a Subject of Study.*—In a comprehensive view of the diseases which we are called upon to study, three only are of wide and universal interest—tuberculosis, cancer, and syphilis. In almost every particular tuberculosis out-tops the others. It is a disease of extensive distribution among animals, in which the veterinarian is interested equally with us. The general surgeon must know it thoroughly, and it occupies his thoughts almost as much as cancer, and his hands more than syphilis. The specialist must be familiar with its manifestations. Though not a disease upon which the specialist thrives, the laryngologist, the neurologist, the gynecologist, and the dermatologist see cases almost daily. Syphilis has a more enduring grasp, and, not content to follow man from the cradle to the grave, nips the fruit in the bud, and more often brands and maims than kills. Tuberculosis and cancer respect the embryo, and are not factors in intrauterine pathology. In many ways syphilis is the most benign of the three. There is a silver lining on the luctic cloud, which we never see in cancer, and not often enough in tuberculosis. And yet tuberculosis, which is a more serious disease than the others combined, offers a greater hope of a reduction in its ravages. We know the cause, the conditions under which the germs thrive and the modes of infection, and the public is at last awake to the importance of the subject, as shown by the remarkable manifestation of national and civic interest during the past few years. We have reached agreement on two points; first, the right of the State to insist that a tuberculous patient shall not be a source of danger to others, (and to this end there must be some supervision, to the extent at least of notification of the cases); and, secondly, the duty of the State, of civic authorities, or of private benefaction to provide suitable accommodation for the poor consumptives. The danger is not from the few well-to-do patients, in whose environments there may be less risk of infection than elsewhere. A person would probably run less risk of "catching" consumption in the Adirondacks' sanatorium than living in the tenement districts of New York, or in the Jewish quarter of this city.

III. *The Physician as a Student of Tuberculosis.*—The brunt of the battle in the warfare against tuberculosis falls on the medical profession. We must not only be alive to our duties, but thoroughly prepared to carry them out. If a man looks back on the best work of his life he will find it to be that for which perhaps he has had the least acknowledgment from the public or his colleagues in either cash or credit; and so it must ever be with the work of the units of our army, and particularly in their crusade against tuberculosis. Within the past ten years there has been an extraordinary change in the attitude of the average doctor to the question of consumption; he is more expert in the early recognition of the disease; he appreciates the conditions under which cure may be expected, and he is more ready to take every advantage of the opportunities offered by the health boards and their laboratories; but I must confess he still very often lacks the enthusiasm which is necessary to make a strong fighter. I know how hard it is in general practice, particularly among the poor, to carry out instructions which we rattle off so

glibly or write down with so much self-satisfaction, but physicians cannot escape from their responsibility in this matter. To them the public must turn for help, since they alone can insist that the tuberculous patients shall live a hygienic life, and when all fully realize their duties we may look for a marked reduction in the incidence of the disease. The really serious peril is the prevalence of the disease among the poorer classes, who live in the smaller houses and tenements, who for the most part have no physicians to advise and instruct them, and who seek aid at the hospitals and dispensaries. Two years ago I was much impressed with the number of such cases applying at our out-patient department of the Johns Hopkins Hospital, and some kind friends placed at my disposal a sum of money which was to be used to promote the study of tuberculosis, and to diffuse among the poor a proper knowledge of how to guard against the dangers of the disease. A plan of systematic visiting of each applicant was organized, and Miss Dutcher will speak of her experience during the past year. It was felt that if a well-informed and sympathetic person paid a visit to the house, saw the conditions under which the patient lived, directions could be given with much more likelihood that they would be carried out. Valuable information could also be obtained as to the mode of life and surroundings of these people.

This Society has been organized to promote the study of tuberculosis among the physicians and surgeons of the Hospital, the senior students of the Medical School, and any physicians who may wish to attend our meetings. Believing in the inspiration of great names, we have called it after the name of the greatest student of the disease. An historical review of the great epochs, a minor item relating to the symptomatology of the disease, a critical summary of the conditions relating to tuberculosis in the country at large and in this city, together with a presentation from each of the departments of the work upon tuberculosis in the Hospital during the first decade, will constitute our program for the session.

WHERE THE DANGER LIES IN TUBERCULOSIS.

A Study of the Social and Domestic Relations of Tuberculous Out-Patients.*

By ADELAIDE DUTCHER,

of John Hopkins Medical School, Baltimore, Md.

DURING the past year I have visited in their homes 190 out-patients of the Johns Hopkins Hospital suffering from tuberculosis. These people represent the poorer classes, who are compelled to work on in their illness to support themselves or their families. They are scattered over all parts of the city, but about 85% are limited to particular districts. One large area about the hospital, within a radius of 10 to 15 squares, and extending south-eastward along the harbor as far as Canton. The other district, angular in shape, follows West Baltimore and South Charles streets in a strip from 6 to 8 squares broad and 10 to 15 squares long. Throughout these two districts, which represent the oldest parts of Baltimore, we find the greatest massing of the poor. According to their social and domestic conditions our 190 patients divide themselves naturally into blacks, whites, and

* Paper read at the Laennec—a Society for the Study of Tuberculosis, Johns Hopkins Hospital.

Russians. The Russians are distinguished from the rest of the whites by their exaggerated unsanitary condition.

I have tabulated the details of my observations on the sanitary environment in the individual cases under the following headings: location, crowding, cleanliness, light, and ventilation. Of course, there is no absolute standard that can be taken as a basis, yet according to my impression of the now generally accepted ideas of what would constitute a fair hygienic condition, I consider this summary to be a reasonable estimate of the existing conditions.

SUMMARY OF TABULATION.

Total number of patients	190	{	Whites . . .	130	
Number of houses occupied	231		Blacks . . .	40	
			Russians . . .	20	
			RUSSIANS.	BLACKS.	WHITES.
Bad sanitary location	69%		40%	30%	
Insufficient light and ventilation	83%		71%	46%	
Overcrowding	76%		50%	46%	
Personal and household cleanliness	75%		66%	43%	

These statistics reveal a most distressing state of affairs among the Russians, who are dangerous elements in our midst as breeders and spreaders of this disease. They are fairly well limited to a triangular area bounded by Monument Street, Central Avenue and Jones' Falls. This represents one of the very oldest parts of the city, and the houses now used as tenement houses were originally built for private dwellings. They are packed into these dark, unventilated tenement houses, often families of from 6 to 10 in 2 small, filthy rooms. The halls are never lighted, and seem to be never cleaned. Thus shut in from fresh air and sunlight, living in filth sometimes absolutely beyond description, their resistance to disease must naturally be lowered. We can but fear, therefore, the danger of infection that attends the reckless distribution of tuberculous sputum about the halls and dirty rooms.

The blacks form an intermediate class between the Russians and the rest of the whites. Sixty per cent of them have at least fairly good locations. There is, however, a decided drop in the percentage of other elements that go to make up hygienic environment. Seventy-one percent have insufficient light and ventilation. The houses in the narrow alleys and courts, where so many of them live, are roughly and cheaply built, and have not the facilities for proper light. Fifty per cent of the negroes are overcrowded, and a much higher percentage (66%) are dirty. Their poverty in many instances is extreme. Perhaps on this account there appears to be among them a greater neglect of the sick. One man was found who had been confined to his bed several weeks with almost no care whatever. His father came in daily to bring him a few scraps of food. The poor fellow was spitting at random over everything within reach. His bed and the walls and floor besmeared with sputum were extremely unsightly. Some observations in similar cases were still more disgusting, because made in the season when swarms of flies were found crawling over the walls and bed, feeding on the sputum. It seems unnecessary for me to say here that such individuals should be removed to some hospital or sanatorium, and that someone should be responsible for the disinfection of such rooms.

The colored people seem to be especially careless about smearing their sputum over their clothing. While talking with them I have frequently had occasion to stop individuals from depositing their spit on the corner of an apron or some other garment worn.

Turning now to the whites, who form the most interesting and most hopeful class for the trial of our methods of prophylaxis, the statistics show that 70% have at least fairly good location. In regard to light, crowding, and cleanliness, less favorable percentages present themselves. This only emphasizes the greater need of such prophylactic measures as have here been undertaken.

Though in many cases the facilities for proper light and ventilation are inadequate, yet a large number of the 46% living with insufficient light and ventilation do so because the houses are kept dark and close by keeping the blinds and windows shut. Oftentimes the crowding is not from want of room, but from a natural tendency of the individuals of a household to huddle together.

When the consumptive is ill enough to be confined to the house, it is common to find that he has been given a couch in the corner of the family living-room, which is generally the darkest and closest room in the house. Frequently if the patient finds difficulty in getting up and down stairs, he prefers to spend his nights also on his couch in the corner.

Where large families are crowded into two or three small rooms, the kitchen must also serve as a bedroom, and almost invariably, especially in winter time, the one with a cough is favored with a place in the kitchen close to the fire.

Occupation.—The occupation of some of these patients has a practical bearing on their relation to society. In the majority of cases their occupation confines them within doors. This means that rigid precautions need to be taken to destroy the spit. Individuals at work are prone to spit carelessly about them. When this chance to be on the floor of closed rooms protected from the sunlight, the germs may retain their virulence for a long time. As these germs become stirred up from time to time, they may infect other occupants of the room, or be deposited on the materials worked upon. As an illustration: In a filthy, unventilated room I found four men working on willow ware. One of the men, a consumptive, was spitting about the floor and even on the willows. I feel certain that the other three men were in imminent danger of direct infection.

The sweatshops have a goodly representation among these 190 individuals. Patients often tell me that among the 20, or 30, or 40 individuals who work in the room with them they can point to several who have pulmonary troubles similar to their own.

Not a few of these patients have to do with the handling of food which might easily become contaminated by contact with their soiled fingers. In our list we find cooks, bakers, cracker packers, and keepers of little milk and meat shops represented.

Following the studies of Flick in Philadelphia, the Board of Health of New York City has demonstrated, by the results of an investigation made to determine the distribution of tuberculosis in that city, that much importance attaches to the idea of house infection. Their statistics show that tuberculosis is not uniformly distributed, but that the bulk of the cases are confined to narrow limits in certain streets and houses. They have noted the development of cases of tuberculosis in families that have successively occupied these houses. A look at their maps shows that sometimes six or eight patients were in a house at one time. I might state here that in several instances I learned that patients had developed the disease subsequent to

occupation of houses previously occupied by tuberculous patients. Several times I found two patients, and on one occasion four patients, living in the same house. In all these cases they were members of the same family.

While my statistics are too limited to admit of any conclusions, they do point to the rapidity with which Baltimore houses are becoming centers of infection. During the brief period that these 190 cases were under my observation they had occupied 234 houses. When the tuberculous occupants move out new occupants move in without any attempt at disinfection. In 58% of these cases the family history was absolutely negative, which suggests the possibility of a general source of infection, and may we not look to infected houses as one of the most important?

My work has been to visit these tuberculous patients in their homes and give them a few simple instructions on the nature of their disease, the mode of its contagion, and methods of its prevention by the cultivation of habits of cleanliness, the destruction of the sputum, and the admission of air and sunlight into their houses. In many instances among these poor people the patient can and will be given a sunny room in the house, in a measure isolated from the rest, with very little inconvenience, when they learn that any benefit may be derived from such a step. Most of the patients and their families as well are absolutely ignorant of the idea of contagion. The few that have begun to look upon the disease as communicable, because of their ignorance of the mode of infection and methods of prevention, live in deadly fear that they transmit or contract the disease. To such the information that the elements of contagion are in the sputum, and can be destroyed, is heralded with gladness. If the physician has not informed the patient as to the exact nature of his disease, I have not found it necessary to do so. It is enough for him to know that it is transmissible, be it in his mind throat-trouble, catarrh, or bronchitis.

The need of this kind of education of the public by house-to-house visitation is intense, and I feel that most of these individuals, unless it be the Russians, are teachable.

When we have taught the tuberculous patient to destroy his sputum, to rid his room of carpets and other germ catchers, and to throw open his windows to admit the sunshine and fresh air, we may then begin to look for a visible decrease in the tuberculous entries on our dispensary records.

The statistics of the Board of Health of New York City show a remarkable decrease in the death-rate from tuberculosis since they began a systematic education of the tuberculous poor, and the disinfection of tenement houses occupied by tuberculous patients.

On account of limited time I can but feel that my work lacks thoroughness. To really follow these cases by repeated visits has been impossible. Nevertheless I am happy to say that in the few cases in which subsequent visits were made I found visible signs of an effort to follow my directions. I recall one case in particular. At the first visit I found my patient, a young man of 21 (the oldest of 5 boys, all at home), spitting at random into his handkerchief, or into the sink, or on the floor, just as he found it most convenient. Dried sputum was in evidence all about the room, which made it very disagreeable for the rest of the family. Not one member of the family had had the least suspicion of fear of contagion. At a second visit, one week later, I found that the floor had been scrubbed

with lye, and the patient was carefully collecting his spit in a vessel containing antiseptic fluid. The mother showed herself to be especially grateful for my few words of advice and warning.

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By DELANCEY ROCHESTER, M.D.,

of Buffalo, N.Y.

Associate Professor of Medicine, Medical Department, University of Buffalo.

"THE general and local symptoms, including the physical signs, may afford merely a strong suspicion of the existence of phthisis, and in such instances repeated examinations of the sputum for the bacilli are imperative, and only when they are found is the diagnosis set at rest.

"There are not a few cases in which the physical signs are clearly obvious and in which the bacilli are either not at all detectable or only after several examinations; and the fact that a certain diagnosis is made possible only by the demonstration of the bacilli in the sputum in the incipient stage of the affection, makes a continued search for the microorganisms the first duty of the physician, in cases presenting suspicious signs and symptoms."

I make this quotation from one of the later works on practice, because I believe it is not a true statement of the case, and that a positive diagnosis of tuberculosis can be made in many cases before the bacilli have appeared in the sputum. I desire to call attention to some congeries of symptoms and physical signs from which a positive diagnosis of pulmonary tuberculosis may be made before the appearance of bacilli in the sputum. In the mode of onset the disease may symptomatically point to the digestive system, the circulatory system, the lymphatic system, the blood or the respiratory system, or to any group of two or more of them.

The following cases illustrate some of these points:

July 25, 1895, J. B. F., male; single; age, 30; occupation, paperhanger. Family history, negative. Personal history, good habits; no sickness until April last, when he was sick with a fever pronounced by a physician to be typhoid fever, and by another pneumonia. Since this sickness patient has not felt well, has lost in weight 29 pounds since February; his voice is husky and he coughs a little every morning, but has no expectoration; complains of weakness, shortness of breath especially upon exertion, and a feeling of oppression in his chest.

His appetite is good, his bowels regular. He sleeps well. His pulse, 110, small and weak; temperature, 99° F.

His pharynx is normal; posterior wall of larynx is a little swollen so that the vocal bands do not come well together; though the bands themselves are in normal condition.

Physical examination of chest shows slightly diminished movements on the right side and impaired resonance noticeable particularly in the right supraclavicular region, and in both infrascapular regions; breathing slightly roughened in the right supraclavicular and infraclavicular regions; the heart-sounds transmitted with considerable intensity in the right infraclavicular and supraclavicular regions; the vocal resonance slightly increased in same regions.

This case was diagnosed as one of pulmonary tuberculosis, probably. This probably was changed to positively in August, when there developed bronchial breathing in right supraclavicular region and a few moist rales in the same place. A slight amount of

sputum was obtained at this time, which was mucopurulent in character, and contained pus-cells and organisms, but no tubercle-bacilli or pneumococci.

This case was under observation for 11 months and improved steadily for 6 months, when he had an attack of influenza and from that time lost ground. In May, 1899, physical examination revealed bronchial breathing and fine rales in right upper lobe, and coarse rales elsewhere on both sides. Sputum did not yet show tubercle-bacilli. He went to Denver, and while there, although his physical condition improved, the organisms finally showed in the sputum.

In this case the diagnosis was made when there was very little sputum and that without the organisms in it. The history, the symptoms, and the physical signs made the diagnosis easy.

Another case: July 21, 1897, C. Y., female, aged 21, shop-girl. Family history good; personal history, scarlatina 7 years ago. No other sickness. For the last 2 years has suffered more or less with nausea, and has slowly and steadily lost weight; 34 pounds lighter now than formerly.

She is weak, anemic, poor appetite, bowels regular, with tendency to looseness; menstruation regular, but painful. Her pulse 90, small and weak; temperature 99.8°.

She has almost no cough, but has occasional expectoration; no tubercle bacilli in it. Her heart-sounds are good, except for a slight systolic murmur heard in the pulmonary area, and an accentuated closure of the pulmonary valves. The heart-sounds are heard with considerable intensity in the right infraclavicular region. There is some depression in the right supraclavicular and infraclavicular regions, a slightly impaired resonance, and a prolonged, high-pitched expiratory murmur. The vocal resonance is slightly increased in intensity in both of these regions and in the right suprascapular region.

This case I consider one of pulmonary tuberculosis, although bacilli have never appeared in the sputum. In fact she ceased to have sputum, and all physical signs disappeared except a slight depression around the right clavicle, and a slight impairment of resonance in these regions and the right suprascapular.

She came under my observation again on October 23, 1900, with a few moist rales in the right infraclavicular region, but no tubercle-bacilli in her sputum. Under treatment the rales have disappeared, and she is improving in all respects. This is a case of tuberculosis that has been recognized early enough to be properly treated and not go on to the breaking-down stage when the bacilli show themselves in the sputum. I have several other similar cases in young women, chiefly shop-girls.

Another case: W. B., male, American, aged 55; married; bartender. Family history, good. Previous personal history: measles, scarlatina and mumps in childhood; gonorrhea and syphilis (?) 17 years ago; a year ago had delirium tremens followed by pneumonia. From this he recovered, but has never felt well or strong since.

October 20, 1900, he had a chill and felt miserable and weak and sick, with recurring chilly feelings. October 23, he developed a pain in the right hypochondriac, lower axillary and infrascapular regions, which was increased on deep inspiration.

Patient entered the Buffalo General Hospital October 29, 1900, in the service of Dr. Charles G. Stockton. His temperature was 99° F., pulse 88, respiration 22. After he entered his temperature persisted between 99° and 100.4°, his pulse was 80 or a little over, and his respiration 22 to 28, until November 4, when his temperature dropped to 97.2°, pulse to 72, and respiration to 22. From November 4 to November 7 his temperature has varied from a morning temperature between 97° and 98° to afternoon temperature of 99° or a little less.

Unfortunately, there is no recorded physical examination

at the time of his entrance. His sputum, examined November 1, by Dr. T. B. Carpenter, is described as follows: Color, yellow; odor, foul; reaction, acid; consistency, semifluid; character, purulent. Microscopically, it was found to contain leukocytes, small and medium sized round cells and a few red blood cells. Bacteriologically, it showed the presence of staphylococci, streptococci, diplococci and bacilli. There was not found *Bacillus tuberculosis*, *Bacillus influenzae*, or *Diplococcus pneumoniae*. The examination of the urine revealed a normally functioning kidney.

I saw him November 7. The physical examination of his chest is as follows: Slight depression in both supraclavicular regions. Diminished expansion in right supraclavicular region. Vocal fremitus increased in right supra- and infraclavicular and mammary regions. Percussion resonance diminished in intensity, and high in pitch in right supraclavicular and infraclavicular, mammary and axillary regions. On auscultation, the heart-sounds are found to be transmitted with distinctness to the right supraclavicular and infraclavicular regions, but not to the left. The heart itself is in good condition, except that the pulmonic closure is a little accentuated.

In the right supraclavicular region there is diminished vesicular breathing with prolonged expiration, the vocal resonance is increased, and there is whispered pectoriloquy during expiration.

In the infraclavicular, mammary, and axillary regions of the right side, the vesicular breathing is decidedly diminished in intensity. In the third intercostal space, between the mammillary and anterior axillary lines, there is prolonged expiration, not loud, but of distinct bronchial quality; and there is also a slightly bronchial quality to the transmitted voice.

Posteriorly there is impaired resonance in the right suprascapular, scapular, and interscapular regions, and slightly diminished resonance in left suprascapular. On auscultation there is prolonged expiration, high in pitch in the left suprascapular region; in the right suprascapular, scapular, and interscapular regions, the inspiration is decidedly diminished in intensity, and the expiration is prolonged and high in pitch. There are coarse, moist rales here and in the infrascapular region. The vocal resonance is slightly increased on the right side throughout.

In this case the history, symptoms, and physical signs all point to a pleurisy of the right side and a concomitant bronchitis with patches of bronchopneumonia. While I do not think in this case that the whole process in the lung and pleura is tuberculous, I do feel confident that in the upper right lobe there is a tuberculous infiltration. The signs that point to infiltration are there, and the organisms found in the sputum are not those that produce persistent infiltration of the lung. Under the circumstances, it seems to me but rational to refer the condition to the most common cause of localized infiltration of lung, viz., the tubercle-bacillus. The case is being treated on the diagnosis of pulmonary tuberculosis.

Another case is one of a young woman, a nurse, who had a severe attack of bronchitis in June, 1900. The case was one of apparently ordinary bronchitis, but quite severe in its manifestation. The physical signs were apparently equally distributed through both lungs and cleared up entirely as she improved. She recovered in all respects except one. Her temperature persisted a trifle above 99° every afternoon. Her morning temperature was 97.5°, or 98°, or 98.5°, the afternoon temperature being from 0.5° to 1.5° above the morning.

The only organism in her sputum during the attack was *Diplococcus pneumoniae*. During her convalescence, the sputum ceased entirely.

On account of this persistent temperature following an attack of bronchitis, I advised her going to the Adirondacks, for I felt certain that the case was tuberculous. She went and improved decidedly; her temperature came down to normal, and she wished to return after 6 weeks. I advised her, before returning, to take diagnostic injections of tuberculin. Dr. Trudeau gave her 0.001 gm. There was only

a half degree rise in temperature. Four days later she received 0.02 gm., and had a pronounced reaction. She has decided to remain there this winter.

With these cases as a text, I wish to state the symptoms and signs upon which I place reliance as positive indication of pulmonary tuberculosis. These are the history of cough, or a present existing cough, with or without expectoration; a difference of a degree or more between the lowest and the highest temperature in the 24 hours; loss of strength or weight, or both; anemia more or less pronounced; diminution or cessation of menstruation; the occurrence of night-sweats, even though only occasionally; the history of, or the present existence of, enlarged lymph-glands in the neck; the persistence or development of cough after any of the acute infections.

If cough and any other one of these symptoms are present, it is important to make a very careful examination of the chest. The first examination of the chest in a given case for the purpose of diagnosis should be made with the chest absolutely bare to the waist. A light sheet or blanket may be thrown over the back when the front of the chest is being examined, and over the front of the chest when the back is being examined, but all other covering should be removed. It is absurd to pretend to thorough examination with only a small space of chest uncovered at a time. The earliest signs show themselves, as a rule, at the apex of one or the other lung; in my own experience, the right lung has been first affected in the great majority of cases. The signs that first show are, on careful scrutiny, a slightly lessened movement in either the supra- or the infraclavicular region; the diminished expansion on one side can often be appreciated only by carefully comparing corresponding intercostal spaces with each other. Usually at this stage the vocal fremitus, as transmitted to the hand, is not affected. A slight diminution in percussion-resonance is the most suggestive sign of beginning infiltration or localized pleurisy. Even a slightly high-pitched resonance without real diminution in the resonant quality is usually indicative of beginning infiltration, except when it is found only in the right infraclavicular region where in a certain number of cases there is normally a slightly higher pitched note than on the left side.

One of the early signs on auscultation is a breathing slightly diminished in intensity, particularly if this diminution is chiefly noted during inspiration and the expiratory sound is prolonged, even though the pitch of the sound may not be materially altered from the normal. This change in breathing may often be noticed only in the supraclavicular or suprascapular region. Occasionally we get a true bronchovesicular breathing in the outer part of the scapular region, together with a slightly bronchial quality to the transmitted voice-sound.

The increase in vocal resonance and the occurrence of the expiratory whispering soughle or whispering pectoriloquy associated with prolongation of expiration, if heard in the supraclavicular region, are, I think, proof positive of infiltration and, if associated with any two or more of the previously enumerated symptoms, of infiltration of tubercular origin.

Another important sign of infiltration of right lung is the transmission of heart-sounds, first and second, to the infraclavicular region of the right side. The occurrence of a cardiorespiratory murmur just below the clavicle means, I think, an adhesive pleurisy making

traction or pressure on the subclavian artery or vein, and is an additional evidence of involvement of right lung, but is not so certain as the transmission of the heart-sounds themselves.

If in addition to any of these signs there are moist rales to be heard, as in the case of the shop-girl related, the diagnosis is made so much the more sure. Even in cases who have no cough, if two or more of the symptoms, enumerated at the beginning of this paper, are present, a careful examination of the chest is in order.

If in a given case the physician is not really certain of the diagnosis, or the patient requires to be convinced, I feel sure that in tuberculin we have a most valuable diagnostic aid. The case of the trained nurse, cited above, illustrates this point. Of course tuberculin should be administered only by a physician and with the strictest aseptic precaution. The temperature should be taken and recorded every 2 hours for 36 hours before the administration and for 24 hours after. One milligram should be given as the initial dose. If no reaction occurs, at least 4 days should elapse before giving the second dose, which may be 2 milligrams. In case there is no reaction to this dose, 4 days later 5 milligrams should be given. If no reaction occurs to this, the case may be said to have in it no tubercular focus capable of ignition; that is, no tuberculosis. If there be tuberculosis reaction will occur and no harm will be done to the patient. The patient will be convinced that he must care for himself and will consequently be benefited by the early diagnosis of his condition.

From what has been said, I hope that I have made plain that the most important diagnostic procedure is the very careful and very thorough physical examination of the chest and the careful comparison of corresponding areas on the two sides with each other. By such careful examination I believe that the vast majority of cases of pulmonary tuberculosis could be recognized before the bacilli have appeared in the sputum.

However, I do not wish to be considered as in any way belittling the value and importance of frequent and careful examination of the sputum in every case of sickness that has sputum. Only this fall there has occurred in my practice a case illustrating the point. In the middle of October, L. H., a medical student, was attacked with bronchitis which ran the course of an ordinary bronchitis. The sputum showed *Diplococcus pneumoniae* in pure culture. The temperature subsided, the patient felt better, and finally the cough ceased, except an occasional cough. The physical signs disappeared. Nevertheless, I told the young man that as long as there was any expectoration to bring a 24 hours' sample around every third day. The fourth such examination, when the total amount of sputum was not more than 2 cc., showed the tubercle-bacilli in considerable number.

Now, the physical examination shows a beginning infiltration of the upper right lobe. The whole secret of diagnosis is careful and persistent study of each case.

The Army Veterinary Corps.—The military veterinary corps has commenced its active campaign in behalf of legislation for an organized veterinary corps in the Army, as provided for in section 14. The committee on Army legislation, made up of members of the association, have asked the support of Congressmen of the veterinary section, as it stands, as part of the first army reorganization bill which passes Congress.

SOME OBSERVATIONS ON THE OCCURRENCE, EARLY DIAGNOSIS, AND TREATMENT OF INCIPIENT PULMONARY TUBERCULOSIS IN DISPENSARY PRACTICE.*

By HENRY L. SHIVELY, M.D.,

of New York.

Physician to the Presbyterian Hospital Dispensary, Department of Heart and Lungs.

THE rigorous exclusion of consumptives from general hospitals, made necessary by the assignment of tuberculosis to the group of infectious and communicable diseases, and the inadequate provision made for this numerous class in the few existing special institutions, have made the lot of the tuberculous poor in large urban populations indeed a hard one. Housed in crowded tenements and sleeping in ill-ventilated rooms, excluded from sunlight and pervaded by the noisome odors of unsanitary living, with improperly prepared food, deficient often in quantity or quality, it is sufficiently obvious that for the majority of phthisical patients applying for relief in city dispensaries, the conditions for treatment are much less favorable than are those appertaining to patients blessed with ampler fortune. Indeed, it has been said by an eminent authority some 15 years ago that the prognosis in phthisis is almost entirely a question of money. That this discouraging view does not hold with equal force today is evidenced by the steadily declining death-rate from tuberculosis and the relatively less importance attached by the profession to climatic treatment requiring change of residence and long and costly journeys to distant health resorts. For the class of patients here considered sanatorium methods are not yet generally available and doubtless will not be for many years to come. What, in the meantime, can be done for the consumptive poor as outdoor patients until some better provision is made for them either by State or by private beneficence?

In a considerable number of cases, occurring even amid the unfavorable surroundings of dispensary practice, recovery is possible, and for nearly all incipient cases improvement may be expected. And first let it be insisted that it is not so much an ideal specific which is needed in the treatment of tuberculosis as an early recognition of the disease and intelligent cooperation of the patient with the physician in carrying out for a sufficient period of time the simple hygienic and therapeutic measures which are everywhere readily attainable. Even if a specific treatment were to be discovered it cannot avail after extensive tissue changes and destruction of pulmonary substance have occurred. Of the greatest importance, then, in any case is the matter of an early diagnosis which in practice cannot be separated from successful treatment.

There appear to be presented two fairly distinct types which are especially liable to develop tuberculosis. The one in its most characteristic expression is the florid, sensitive person of nervous temperament and quick intelligence, with delicately chiselled features, oval face, fair, fine hair, large lustrous eyes with arched brows, thin, smooth, hairless skin, complexion of sea-shell tints, small bones, slight, graceful figure, and tapering fingers with long almond-shaped nails. The other type finds its most complete example in the sluggish, mentally inferior immigrant from Southern Europe with high cheek bones, irregular features, rough, thick skin, sallow complexion, large, ill-shaped hands with clubbed finger-

tips and nails of marked convexity, coarse, dark hair and thick, large bones. This latter class is not so well defined perhaps as is the former; both may appear to be somewhat fanciful, and there are, of course, many cases belonging to neither; but among the tuberculous poor of New York there are a sufficient number of patients with more or less one of these sets of characteristics to make their recognition of some value. In connection with these minor features of interest there may also be frequently observed, in cases of incipient pulmonary tuberculosis, a pinched nose of peculiar waxy pallor, against which the brownish-yellow orifices of the sebaceous ducts stand out like dots in marked relief. This anemic, dotted nose may be present when there is but little or no general emaciation or anemia. A similar appearance of the chin has occasionally been seen. In the nose the appearance is most marked at the tip and lower third.

Dyspnea on exertion and rapid heart-action are symptoms sometimes occurring very early. Indeed, from the intimate physiologic and anatomic relations existing between the heart and lungs through the pulmonary circulation, it might be *à priori* expected that there is more than an accidental relation between pulmonary tuberculosis and functional and organic heart-disease. From the frequency with which valvular lesions of the heart are found in the examination of tubercular chests, it can hardly be doubted that organic cardiac disease may be regarded in some cases as one of the predisposing causes of tuberculosis of the lungs. It may readily be conceived that a disturbed or sluggish pulmonary circulation, resulting in deficient oxygenation of the blood, hypostatic congestion and impaired vitality of the lung tissues, together with general anemia, supply both the local and constitutional conditions favorable to bacillary infection. Pulmonary hemorrhages are sometimes of early occurrence and when present should be carefully distinguished from epistaxis and bleeding from the mouth and stomach. Neuralgic pains, which are common in advanced cases, may also be felt very early in the disease. They may be limited to the affected side of the chest, or may be felt on the opposite side, or in the back and limbs, and are to be regarded usually as symptomatic of a general anemic condition rather than as of local origin. Somewhat exceptionally in this early stage there may be similar and more severe pains in the chest, due to a localized dry pleurisy, or felt elsewhere and caused by a true peripheral neuritis. Chilly sensations and abnormal sensitiveness to cold may be early noticed. A careful observation of the temperature will usually show a continued daily elevation of a fraction of a degree or a degree in the afternoon. A subnormal early morning temperature is also significant. If other causes for these thermometric variations can be excluded, and if they occur in a person with progressive loss of weight, failing strength, poor appetite and anemia, developing tuberculosis may be suspected even in the absence of cough and physical signs. Of the latter, one of the earliest of value is the jerking, interrupted, "cog-wheel" inspiration over the apices, which may sometimes be heard before dulness in the percussion note can be detected. In healthy adult chests expiration is scarcely audible and any prolongation or considerable increase in its intensity should be regarded with suspicion. Decided increase in the whispered voice may often be elicited before there is much alteration in the spoken voice. In estimating the voice and breathing and vocal fremitus,

* Read before the West End Medical Society of the city of New York, November 3, 1900.

due allowance should be made, however, for the difference in the size and location of the right bronchus. On account of its larger caliber and higher division there is normally over the right upper lobe an area of louder breathing and greater voice sound and fremitus, situated below the clavicle and to the right of the upper end of the sternum. This may cause error in being interpreted as due to pathologic change, especially in persons with thin chest-walls. Among the minor changes which are of some value in connection with other signs are sinking in of the spaces above and below the clavicles and dilation of the superficial veins of the chest above the nipples. Chromophytosis of the skin over the chest and shoulders is frequently seen in the examination of tuberculous chests.

The detection of the tubercle-bacillus in the sputum is of course of the greatest importance, but unfortunately in the earliest stages bacilli are frequently not present, and as a practical aid the microscopic examination will often be corroborative rather than primary in establishing the early diagnosis. In many cases the skillful clinician will have sufficient reason for suspecting the existence of tuberculosis before the bacilli can be demonstrated or indeed before cough or sputum is present. The tuberculin test, which is so valuable in veterinary science in establishing the presence of bovine tuberculosis, should not ordinarily be employed in man on account of the occasional severity of the reaction and the possible danger of lighting up quiescent foci of infection. Its use will be but rarely necessary. Should it be employed at all it should be remembered that the reaction also occurs when syphilis is present. A limited experience with the application of the Röntgen-ray and fluorescent screen to the examination of chest cases would indicate that although often affording a beautiful demonstration of the extent of tuberculous lesions in advanced cases, it is doubtful whether they can give any material aid in the early diagnosis of incipient disease.

In the examination of the patient, in addition to the signs and symptoms due to the actual presence of active tuberculous processes in the lungs, evidences of tubercular lesions in early life should be carefully sought for, such as cicatrices remaining from suppurative adenitis of the cervical glands, ankylosis or atrophied limbs—the effects of tubercular bone and joint diseases, enlarged glands, and scars from cold abscesses. The frequency with which pulmonary tuberculosis has been observed to follow an attack of pleurisy with effusion may cause the family physician to view with apprehension a tardy or lingering convalescence from this disease. The co-existence of saccharine diabetes and phthisis so often seen should cause a careful examination of the chest to be made when sugar has been found in the urine. The development of an ischiorectal abscess or the long continuance of a sluggish fistula in ano may point to latent tuberculosis of the lungs. Among boys and young men from 16 to 20 a sufficient number of cases have been observed to create a strong presumption in favor of the belief that the practice of smoking and inhaling cigars to excess may be a factor in the causation of consumption. When the disease exists even among adults excessive smoking should be discouraged, and if permitted at all should be limited to one or two cigars or pipes a day. The special evil of cigaret-smoking is that in this form, smoking is apt to be more or less continuous throughout the day and the practice of inhaling the smoke in the lungs is almost universal.

The family history should be minutely inquired into, or rather the personal history of the case in its relation to other cases of tuberculosis, for heredity is now deemed to play at most an unimportant and rather doubtful etiologic role. Cases developing in the same family are rather to be accounted for by the greater exposure to sources of infection, and the frequency of transmission from husband to wife, or wife to husband, or from patient to nurse, when proper care of the sputa has not been observed, would go far to establish this view. As bearing upon this point I have been able to collect from the case-books of my service at the Presbyterian Hospital Dispensary during the past five years, 75 cases of pulmonary tuberculosis acquired by healthy persons with no tubercular family history under circumstances which point to direct infection. Of this number 71 were cases in which the disease was acquired after marriage, the family of the healthy conjugal partner having been free from tubercular disease so far as could be ascertained. A striking fact in the analysis of these cases is the great preponderance of wives over husbands who thus acquire the disease, for of these 71 cases in but 10 was the husband infected from his wife. It would thus appear that the risk for a woman in marrying a consumptive is fully six times greater than the corresponding risk for a man. This disparity may in a measure be accounted for by the less robust constitution of the female, the indoor life she leads, the effect of frequent childbirth in quick succession, and prolonged lactation. In one case a consumptive man, who has also had a tubercular arthritis of the kneejoint, has infected two wives, the first having died of phthisis, the second is now also under treatment with him at the dispensary. A striking instance was the case of a healthy lad, 17 years old, in whose family there had never been consumption, who developed tuberculosis of a rather acute and rapidly progressive type after sleeping with and occupying for three months the room of a man with phthisis. Another case was that of a strong, healthy Irish girl, in whose family there had never been any trace of tuberculous disease, who entered a convent, and during her novitiate was required to attend a consumptive nun far advanced in the disease. After a few months she developed consumption herself and was obliged to relinquish her religious life, leaving the nunnery for treatment. An instance coming under observation some years ago, but not in the dispensary, was that of a healthy child, aged 5, of sound parentage, who shortly after an attack of measles was taken to Southern California in a sleeping-car occupied largely by consumptives. This was before the public or profession generally had accepted the doctrine of the infectiousness of tuberculosis through the sputum, and the conditions in sleeping-cars and steamers to Western and Southern health-resorts, in the light of modern ideas, were horrible to contemplate. Shortly after his arrival in Los Angeles this child developed a persistent cough and died of a tubercular meningitis. During a two years' residence in Southern California it was a matter of common remark that the native Mexican population was prone to develop consumption, among whom, in former years, the disease was practically unknown before the influx of consumptive tourists and health-seekers from the East. A similar observation has been made regarding the occurrence of phthisis among the Italian peasantry of the health-resorts of the Riviera.

It is of course possible for a certain number of these cases to be accounted for by mere coincidence, and de-

ductions of this kind are always liable to error, but in each of these 75 cases the family history was carefully inquired into and is believed to have been free from tuberculous taint. The number collected is probably considerably under the actual number, as in some cases the histories were deficient or doubtful, and all such were rejected. There have been also numerous cases of adults in the same family developing tuberculosis under circumstances which pointed clearly to direct infection rather than to heredity, but these also have been excluded from consideration on account of parentage or kinship which might possibly introduce another factor. The cases here collected are then in each instance examples of previously healthy individuals of good family history who have acquired the disease after marriage or other intimate relation with a tuberculous person. The conviction appears irresistible that there are many cases thus acquired, and that especially for women the dangers of marriage with a consumptive are grave indeed.

The occupation of the patient may to some extent create a presumption in favor of the existence of tuberculosis. The disease is apt to develop in persons who follow sedentary pursuits amid unsanitary surroundings or exposed to the inhalation of dust and unwholesome vapors. Printers, weavers, stonecutters, knife grinders, metal workers, factory operatives, tailors, tobacco-strippers and packers, workers in wall-paper, dyers, painters, and cigarmakers are occupations frequently noted in the case-books opposite the names of dispensary patients. Race does not appear to be a very important factor in the occurrence of tuberculosis in New York except that in a general way people coming from warm, equable climates to our variable one are apt to suffer. Mulatto negroes from the tropical West Indies, Italians from about Naples and Sicily, and Chinese coolies from the south of China near Canton are more apt to develop the disease than immigrants from northern Europe.

When the diagnosis has been established the patient should be frankly told the nature of his disease, explaining its curability, quieting all unreasonable apprehensions and securing his cooperation by stating that ultimate recovery will depend largely upon his faithful compliance with the hygienic instructions given and the continuance of the treatment for a sufficient time. It has been well said that the consumptive must make a business of getting well. It is a mistaken kindness to gloss over his condition, as is so frequently done through reluctance to alarm him or his friends. A case of incipient phthisis, when told that he is "run down," has "a bad cold," "bronchitis," "asthma," or "a touch of malaria," is almost certain to neglect treatment at the most hopeful period of the disease. Such an opinion from his physician, with the optimistic temperament so common in tuberculosis, readily produces a false sense of security, and thus the insidious progress of the disease is but too often unopposed. On the other hand the most timid and sensitive patient can, by the exercise of tact and by the comforting assurances of the results of treatment, be made to realize the possible gravity of his complaint and yet enter hopefully and confidently into the campaign against it. The importance of the role played by the patient himself in his recovery cannot be too strongly emphasized.

He should be told to spend as much time as possible in the open air, and the cultivation of an erect attitude with the shoulders back and chest forward should be advised. Twice a day or oftener the inflation of the

chest by a series of gentle, deep, prolonged inspirations and forced expirations, when the practice does not provoke coughing, is useful. The living and sleeping room should be the largest and best ventilated available. In the tenements and small flats occupied by most dispensary patients the sleeping rooms are usually small and either without windows or opening on a stuffy, cramped, dingy air-shaft. These small bedrooms and the kitchen are the ordinary living rooms. The one room opening on the street and accessible to abundant sunlight and air is usually least occupied by the family and is the one to which the consumptive patient should be removed. Where it is possible he should sleep alone. He should be instructed to avoid exposure to cold and damp, and it is undesirable for him to frequent crowded halls and places of entertainment where the air is vitiated. Woolen underwear, but of lighter weight in summer, should be worn next the body throughout the year. The entire surface should be uniformly clad, discouraging all coddling with the popular red flannel chest protector or the familiar porous plaster. The use of water in the form of the daily sponge bath, followed by brisk friction with a rough, huck towel, is a wholesome practice. If there is fever or night-sweats the bath is better taken in the afternoon or at night before retiring, otherwise the first thing on rising. At first the bath should be warm enough to avoid chill or shock, but the temperature should be gradually reduced until cold water can be used. The addition of a little alcohol or spirits of camphor to the water may be recommended. The bath in the evening, besides its desirable effect on fever and night-sweats, is often useful in promoting sleep. In afebrile cases moderate exercise may be permitted, always stopping short of the point of fatigue. Chest-weights, light dumb-bells or Indian clubs may be cautiously used, but never as a substitute for or to the exclusion of exercise in the open air. In progressive cases exercise of any kind is undesirable.

The patient should be carefully instructed as to the proper care of sputa, an appeal being made to his instinct of self-preservation by telling him that not only is there danger of infection to others, but that his own condition may be made worse by the inhalation of infective material. He should be specifically told to exercise care to avoid soiling his clothing and linen. Handkerchiefs are not proper receptacles for sputa. When away from home, pieces of cloth, or better, Japanese paper napkins, which are inexpensive, should be employed for this purpose. When soiled they are folded and inclosed in a stout envelop which, with contents, is burned as soon as convenient. At home the crachoir should have a sufficiently large opening to avoid soiling the sides and should contain either plain water or a solution of a simple disinfectant. The patient should be cautioned against swallowing his sputa, as there is good reason to believe that this practice is frequently a cause of intestinal tuberculosis. If there is any obstacle to free nasal respiration it should be corrected by appropriate treatment. An examination will often reveal a hypertrophic rhinitis, polypus, spur, deflected septum, or adenoids.

In the diet of the consumptive the keynote is the administration of milk, and its assimilation by the patient will often afford a reliable indication of the prognosis. In my experience patients who can take large quantities of milk, month after month, usually do well. When milk cannot be taken in some form the prognosis is likely to be bad. Too much importance

should not be attached to the patient's statement that he cannot take milk or that it makes him "bilious." The addition of a little bicarbonate of soda, lime-water, or vichy will often make it well borne. Hot milk may agree better than cold. In some cases peptonizing the milk may be necessary or matzoon or koumiss may be tried. In summer buttermilk is often relished for a change. For an adult as much as two quarts of milk a day is desirable, and where it is taken well a little cream may be added. In addition to the milk when the patient's stomach is in good condition, a full nitrogenous diet with an abundance of fats is advised. Broiled steak and chops, roast beef, eggs, poultry, oysters, soups, and a liberal quantity of butter are recommended. Pork and veal are excluded and the starchy vegetables are restricted. Cereals should have a minor place in the dietary. If milk cannot be taken the next best thing is malt liquors in moderation, such as beer, ale or stout, but I never advise them when milk agrees.

As regards drugs, the best routine treatment is the administration of creosote or some of its derivatives with codliver oil and some preparation of malt. During the hot weather of the summer months the hypophosphites may be advantageously substituted for codliver oil for a time. Nothing, however, can replace the latter as an easily assimilated fat and valuable tissue food, nor are any of its numerous commercial derivatives or so-called active principles to be considered as representing it. When it is well borne the pure oil may be taken. Children often become fond of it, and poor patients can obtain it fresh and of excellent quality at the fish markets. The amount of creosote given daily is from 24 to 60 minims, preferably in the form of an enteric salol or keratin-coated pill of 3 to 5 minims each, which is not dissolved until it reaches the intestine, thus avoiding the gastric disturbances so often occasioned by the drug. There is no advantage in giving it in the enormous doses sometimes advised. It may also be given with glycerin and whisky, in emulsion or shaken up with milk. Sometimes guaiacol or creosote carbonate or thiocol, which is freely soluble, agree better with the stomach, but are too expensive for general dispensary use. I was well impressed with ichthyol in one case complicated with tubercular infiltration of the pelvic floor in which it was used locally with good results. I have since tried it internally in a series of 60 cases, giving 10 minims every 4 hours. Of these cases 29 reported regularly for treatment and of this number 25 were much improved, gaining in weight and the temperature diminishing, with a corresponding improvement in all subjective symptoms. The average gain in weight was $4\frac{1}{2}$ pounds, and the highest observed was 10 pounds. In 5 cases it was necessary to discontinue the drug on account of the eruptions and nausea produced.

When the progress of the disease has been rapid, the administration of opium in small doses for a short time is often very satisfactory in its results. Besides its effects in improving cough and arresting hemoptysis when present, it appears to exert a decided tonic effect, changing the entire *morale* of the patient and encouraging him in the beginning of treatment. Of course, it should be given with caution, but I have never seen any tendency to the formation of habit or other bad effect when thus administered. The old combination of opium with quinin and digitalis—the Niemeyer pill—is a valuable one. For neuralgic pains, apply a small cantharidal blister and rub the chest with the following liniment:

Menthol.....	3	drams.
Chloroform.....	3	drams.
Chloral.....	$\frac{1}{2}$	ounce.
Camphor.....	3	drams.
Alcohol, enough to make.....	4	ounces.

For night-sweats, the afternoon bath and friction, or the administration of atropin or agaricin, are usually efficient. In some persistent cases, potassium tellurate in daily doses of half a grain at night will relieve when other drugs fail. For blood-spitting and hemorrhages, opium and rest, with iced compresses to the chest, are employed. When sudden and profuse, a full hypodermatic injection of morphin should be given. But little dependence can be placed on internal hemostatics. When the appetite is poor, bitter tonics such as gentian, cinchona and *nux vomica* or strychnin are useful. Iron in any form is of very doubtful value in the anemia accompanying an active tubercular process. When there are high afternoon or evening temperatures, the temporary administration of antipyretics—one dose of phenacetin or acetanilid early in the afternoon—are sometimes useful; but generally the fever can be controlled by baths and other treatment.

Grafted upon a chronic tubercular inflammation there may be acute attacks of bronchitis and bronchopneumonia, which are treated as when they occur alone. For irritating, nagging cough, unaccompanied by expectoration, heroin in $\frac{1}{12}$ to $\frac{1}{6}$ grain doses is valuable, as, indeed, it is in all cases of symptomatic cough. It is also useful in relieving dyspnea and chest-pains. Its action appears to be much the same as that of morphin, but its administration in full doses is attended with less somnolence, constipation, and stomach disturbance. Ammonium carbonate, senega, dilute hydrocyanic acid, codein, and hydrobromic acids have been useful palliatives in the cough of phthisis. As a rule, sirupy mixtures should be avoided, on account of their bad effect on the stomach. When the sputum is scanty and tenacious, the administration of potassium iodid will promote freer secretion, diminish the severity of the cough, and add to the comfort of the patient.

In cases of mixed infection, when streptococci swarm in the sputum, when there are severe chills and wide excursions of temperature, with profuse sweating and septic symptoms, I have seen improvement from the injection of Marmorek's antistreptococcus serum, as prepared at the Pasteur Institute of Paris. In one case, after the administration of three injections of 20 cm. each, there was a complete disappearance of the streptococci from the sputum, the chills and sweats ceased, the temperature diminished, and there followed a marked improvement in the appetite and general condition of the patient. In other cases no improvement was seen, or the results were slight or of brief duration. Serum-therapy in general, however, as applied to tuberculosis, has not appeared to have been developed to a point to warrant its extensive trial in dispensary practice.

Such is the plan I have endeavored to follow for five years at the Presbyterian Hospital Dispensary. During the two and a half years ending last June, there have been examined in my class 1,232 cases of tuberculosis of the lungs. Of this number, 948, or more than three-fourths, were under treatment for less than a month, or did not return. Of the 284 cases receiving regular treatment for a period long enough to be of value in obtaining results, 249 have improved. Their improvement has been estimated by recorded increases in weight, reduction in temperature, and betterment of subjective

symptoms. In many instances the improvement has been sufficient to enable patients to return to and continue their usual occupations. Of the 35 cases in which no improvement was seen, 26 were advanced cases and 9 could be properly classed as incipient. I would use the word cure in any case with caution and some hesitancy, but of those under observation for two years or longer there have been as many as 12 cases in which the disease may be fairly described as arrested and in which all symptoms have disappeared.

In conclusion, I would say that it is encouraging to observe with what ready intelligence and willingness most dispensary patients will carry out hygienic detail when properly instructed, and it is obvious what a large and useful field for popular education and sanitary reform is thus afforded in our dispensary classes. It would appear that prevention, by means of widespread sanitation and improvement in the early detection of the disease, constitute the two most promising agencies whereby we may hope to successfully combat tuberculosis.

SANATORIUM TREATMENT AND ITS RELATION TO CLIMATE.

By S. EDWIN SOLLY, M.D.,

of Colorado Springs, Colo.

A RECENT visit to Europe of some 4 months' duration gave me the opportunity of considerably extending my study of the sanatorium treatment of tuberculosis, especially that which is known as the Nordrach system. Descriptive and critical articles upon the noted sanatoria of Europe have been so numerous, while especially accurate information concerning them is readily to be found ably set forth in the works of Dr. S. A. Knopf, of New York, and Dr. F. R. Walters, of London. It is, therefore, unnecessary to lengthen this article with a repetition of what has already been given to the public.

During the 26 years of my practice in Colorado Springs I have seen the use of open-air treatment greatly extended, so that for some years past our patients have passed most of their waking hours out-of-doors, and many during the night have slept on open porches or in tents, and the rest in rooms with wide-open windows. In Colorado we have, as is well known, air which is extremely dry, scant precipitation with an absence of dews, fogs and mists, a brilliant sunlight, and, for the most part, warm days and cool nights, hot sunshine and cool shade. The difficulty in Colorado to be overcome while sitting or lying out of doors is the almost constant movement of air and the comparative frequency of high winds. However, glass screens and other forms of wind shelters have been successfully used to obviate this disadvantage.

In such a climate as Colorado it is not surprising that the open-air treatment can be successfully carried out, but what particularly interested me in my tour was to witness the success that appeared to attend the open-air treatment in the damp, cloudy and frequently foggy climate of England. It seemed to me that if living in the open air was a success in England it would naturally follow that it would be a success in most of the low climates of Europe, and in such a climate as that of the New England States. Indeed, I have seen this treatment being carried out to the satisfaction of both patients and physicians in the excellent State estab-

lishment at Rutland, Massachusetts, under the direction of Dr. V. Y. Bowditch.

The sanatorium treatment may be divided under three heads:

1. The keeping of the patient almost constantly in the open air.

2. Superalimentation.

3. A system of supervision and control.

Not many years ago climate, that is, the quality of the air in which the patient was placed, was considered the essential, and in turn almost every variety of climate was extolled as the best; first the damp heat of Madeira; next the dry heat of Egypt; then the dry, cold, and snow-covered ground of Minnesota; and finally the dry, cold, or else warm, rarefied air of the higher altitudes.

At the next stage it was asserted that purity of air was the only essential, and that the ocean, the mountain, or the wide plain were equally beneficial.

Then followed the setting forth of the opinion that the quality of the air was not important, except that it should be pure, but that that climate was the best in which the greatest amount of out-door life could be carried on, and for this reason and for no other, dry, sunny climates, high or low, were the most desirable.

A further stage was reached when experiments with open-air life in damp, low climates proved a success. It was then declared by the extreme advocates of the open-air treatment that the quality of the air was of no account, it was simply its abundance linked with the other essentials of sanatorium treatment. For instance, in visiting a very excellent sanatorium in England where the Nordrach system was carried out, the able and enthusiastic physician in charge assured me that climate was nothing. He could cure a case in Whitechapel just as well as anywhere else; the system and the abundance of air were the only essentials, Whitechapel being one of the most crowded and poverty-stricken districts of London.

Going first to England I spent some time investigating sanatoria and in conversing with the leading physicians who were principally engaged in treating or advising consumptives, also in gathering the opinions of convalescent or cured patients.

I will mention some of my experiences at the sanatoria. I was certainly surprised to find how well the open-air treatment was succeeding and how little cold-catching occurred among the patients subjected to it. Of course, there were some who could not stand the full air-treatment, particularly during the colder weather. The most of these were those with special catarrhal tendencies, or old fibroid cases, and in whom the amount of lung-space was so limited that the heart's action was interfered with, and the consequent dyspnea curtailed their power to take exercise, thus they did not obtain a healthy reaction to the cold, especially during damp or windy weather.

I stayed a few days at St. Michael's Home, near Cheddar, Wiltshire, in the midst of the famous cheese-making district. St. Michael's Home is a handsome, well-equipped stone building. It is supported by an endowment fund for the benefit of the consumptive poor from London and other big cities. It is under the care of a Protestant Nursing Sisterhood, and one of my sisters is the director of the institution, Dr. Statham of Cheddar being the medical officer. A few years ago Dr. Statham introduced the Nordrach system. I was delighted to find the improvement that had taken place in the condition of the patients since my previous visit.

The change was undoubtedly brought about by keeping the patients out-of-doors most of the hours from breakfast to bedtime. A few shelters were provided for rainy weather. The diet, which had been quite as ample as was customary in homes and hospitals of a similar character, had been largely increased, especially in the matter of milk, the patients consuming a pint with each of their three meals. Further, the matter of rest and exercise had been systematized and regulated with care for each individual, certain definite walks being laid out and prescribed according to the case. The patients themselves were rejoicing in the open windows and open-air life and developed the air-hunger. I was told that those who had returned to their homes were generally heard from as bitterly complaining of the stuffy condition of the rooms where they had formerly lived perfectly contented. As this institution is entirely a charity, no charge being made, the statements concerning the success of the treatment were without the suspicion of any commercial prejudice. The cases for admission were not in any way limited as regards the extent of their disease, consequently their results en masse would not be as favorable as those of the generality of sanatoria where only cases are received which are likely to improve. Having known this establishment under the old regime and the new, I contrasted the happy and cheerful appearance of those under the new system with the sad, hopeless, resigned, and attenuated appearance of the patients under the old, and obtained the most convincing proof that I met with on my travels of the value of the open-air treatment. I gathered that even hopeless cases as a rule lived longer than formerly and ultimately succumbed with a shorter and less weary waiting in bed for the inevitable end.

As regards the local conditions the situation is a good one, being on sloping ground on the side of the Mendip Hills, which afford some shelter from storm and wind. The soil is good, with good drainage. The grounds are ample, with winding paths, and lawns, shrubs, flowers, and trees. It is only a few hundred feet above sea level, and the climate is mild, but is as humid as that of the country generally through the west of England.

About 10 miles distant on the top of the Mendip Hills, the Nordrach sanatorium is situated, which is a private institution conducted by Drs. Thurnam and Gwynne, both former consumptives who had been cured at the original Nordrach Colony in the Black Forest. The Mendip institution is excellently managed, with good buildings and accommodations for the well-to-do, and beautiful grounds well sheltered by pine woods.

Here the climate is more harsh and the country round bleak and exposed. The quality of the cases, being selected before admission, was rather better than at St. Michael's. The results relatively appeared to be about the same. Neither of these institutions have been carried on long enough to speak of permanent results.

Dr. F. R. Walters kindly took me to the North London Hospital for consumptives, of which he is one of the visiting physicians, where the same system is carried out. It is situated high up on the slopes of Hampstead Hill. This is an institution for the poor, but, as at St. Michael's, patients live in large wards and not in private rooms. The grounds are somewhat contracted, as they are placed in the midst of a populous neighborhood, but fortunately the houses around are mostly detached villas and are not closely built up in streets. The hospital has a fine view overlooking the great city of London. The open-air treatment seems to succeed very

well here in spite of the air being only comparatively pure. Probably, however, if an exact comparison could be made it would be found that the results are not as good as at the country sanatoria where the climatic conditions are better.

While the guest of Dr. Burton Fanning, of Norwich, I visited his private sanatorium at Mundesley, Norfolk. This lies on the southerly slopes of a low hill which separates it by a mile from the German Ocean. The building is excellently planned, hygienically and pleasantly situated in ample grounds. Here the patients appeared to be doing well, and Dr. Fanning, who displays a wise and scientific conservatism, was much encouraged.

He has also a smaller institution for the poor, a few miles distant, which I was unable to visit, but where he has also met with success.

Norfolk, being on the east coast, has a bracing and for England a sunny climate and is dry for a sea air.

The report of Sir Hugh Beevor, founded on some recent studies he has made as to the comparative slight prevalence of tuberculosis in Norfolk and its causes, is well worth reading, but cannot here be discussed.¹

I was told that the women did not do as well as the men under the open-air system. This treatment has been carried on in England too short a time to judge of permanent results, but there is no doubt at least that patients are more comfortable and hopeful, and a greater number show improvement for a time at least, than under the old system.

At the Brompton Hospital, which is surrounded by the streets of London and the gardens of which are necessarily limited, the open-air system is being tried and the physicians are well pleased with the improvement of the patients.

Of course, something must be allowed for the success which always follows any new treatment of a chronic disease in consequence of the enthusiasm and hopefulness instilled into the physicians and their patients, and the greater care that is bestowed on the details. But while making due allowance for these considerations I believe that the open-air treatment in England is a distinct advance and has come to stay. While it may only cure a few of those cases in whom the disease is well established, although its enthusiastic advocates believe to the contrary, yet I am of the opinion that where the tuberculous invasion is limited and recent, and before phthisis has well begun, that many tuberculously affected persons will be prevented by this method of treatment from developing chronic phthisis.

In order to study both sides of the question and make comparisons, on leaving England I first visited Falkenstein, which ranks next to Goerbersdorf in being the oldest and most celebrated sanatorium. Then I went to the Nordrach Colonie in the Black Forest, which is the pioneer institution of the more advanced system of open-air treatment and superalimentation, founded and controlled by Dr. Walther. From there I proceeded to Davos in order to see what they were doing in sanatoria in high altitudes, and how the sanatorium treatment compared with that of the open-resort methods for which Davos has been so long celebrated.

The Falkenstein Sanatorium stands on the southern slope of the Taunus Mountains, 1,300 feet above sea-level. It is open towards the southeast, overlooking a most beautiful landscape of plain with growing crops and green fields, while it is sheltered from the north and east and west by wooded hills.

¹ *British Medical Journal*, August 1, 1900.

The main building has two wings joining it at an obtuse angle enclosing a wide terrace 200 feet in length. On either side are two annexes, connected with the main building by covered corridors. Most of the patients lie out during the day upon the covered verandas which project from the buildings. These are protected by awnings to shut out wind and sun as may be required. Dotted about in the beautiful grounds are many small pavilions which revolve upon a wheel placed beneath them so that they can be readily turned away from the wind and towards the sun. The grounds are large and beautiful, with winding walks of gently rising grades. The buildings are heated with steam and well ventilated. The drainage and water-supply is excellent, and the rooms handsome and attractive, though the covered verandas rather detract from the cheerfulness of those on the lower floor.

The climate resembles that of the rest of Central Germany, is slightly bracing, moderately humid, and free from extremes and sudden changes of temperature or high winds, and the air is particularly pure and free from dust.

The whole establishment is most completely equipped with baths, electricity, and means of disinfection, and has everything to make a complete and luxurious establishment. Great care is exercised in the treatment of any morbid conditions with which the phthisical patient may be afflicted in addition to his pulmonary disease, nose and throat treatment being especially well carried out. The patients are kept out-of-doors most of their waking hours, lying on long chairs side by side upon the covered verandas.

The dominating feature of the treatment is rest. The exceptions that are taken to this excellent institution, are that the idea of rest is carried a little too far and that the patients are too much crowded together, and that there is too much shelter and not enough open air on the verandas. The culinary arrangements and the food are of the best and the medical service of the highest order.

The far-famed Colonie of Nordrach has striking features of its own. Here the buildings are quite unpretentious and are scattered about on the sides of a beautiful wooded valley in the Black Forest. It is much further removed from other habitations and highroads than Falkenstein, or, indeed, most sanatoria. The valley stands at an elevation of 1,500 feet, opening towards the southwest. The open-air treatment is here carried out to its fullest extent, except that the patients do not sleep out of doors, as many do in Colorado. There are balconies to some of the rooms, but no verandas or halls for the rest-cure. The patients sleep with wide-open windows and take their meals in a hall where the windows are all let down on three sides except in stormy weather; even then they are seldom more than partly closed.

The numerous graded walks are laid out upon the slopes of the valley walls with benches at certain intervals. When the patients are outside the house they walk, sit, or stand in the open air and generally without their hats. If their temperature indicates that they should be at rest they are kept in bed or lying on couches in their rooms. Certainly there is much less risk of cold-catching from sitting in drafts than in using rest halls and pavilions because the patients are always in the full air. If they cannot stand the exposure they go elsewhere.

Dr. Walther assured me, however that it very rarely happened that a patient could not endure and benefit by this full-air treatment.

Each bedroom has a shower-bath and two basins, all supplied with hot and cold water. One basin is for washing the face and hands, and the other for washing the teeth. The older buildings are heated by hot water, and the newer by electricity. Electric heaters are on hand for the patient to use in bed if needed. Patients dress and bathe as they please and control the opening of their bedroom windows. Dr. Walther insists, however, that at his early morning visit the air of the room shall smell as pure as the outside air.

Doubtless many of the reports about overfeeding of the patients are much exaggerated. The plate of every patient is filled by Dr. Walther himself, and a half-emptied plate is not allowed to be removed before the doctor has seen it and decided whether the patient should be urged to finish the remaining food or whether he can furnish good reasons to the doctor to excuse him from the trying task. There is no doubt that through the doctor's influence over, and his careful study of, each patient, his patients consume on an average a much larger amount of food than at the establishments which are under the old regime. The quality of the food, though good of its kind, is apt to be too teutonic in character, which often makes it repugnant to the British or American stomach. The patients are nearly all of one or other of these nationalities.

The discipline and supervision of the patients is autocratic to the highest degree, although the autocrat is extremely kind and amiable, at least when he is having his own way.

There is no doubt that the treatment at Nordrach has been very successful with many patients; but, on the other hand, there are many who are unable to stand the extreme methods in vogue.

Dr. Walther uses very few drugs and does not appear to pay much attention to the accompanying disorders, or to symptoms except hyperpyrexia, trusting almost exclusively to general hygiene, food, and regular rest and exercise. Perhaps one of the chief reasons, apart from its real value, for the popularity of his treatment is that he allows his patients when their disease is arrested, or as he terms it cured, to return to their former homes. While I met several of his former patients who had returned to their homes in England and were apparently in good health, I heard of others who had fallen behind or succumbed. Of course this is to be expected under any plan of treatment; at the same time I formed the opinion that the permission to once more live at home was, perhaps, too generally given. I have always shared the belief with Dr. Walther that most consumptives live or die according to their strength of character in adjusting their life wisely to their disease, and for this reason many can not be trusted to live again among the environments in which their disease was acquired. However, I believe in the educational power of sanatorium treatment, especially when directed by an intelligent and masterful man, to turn a certain proportion of the unwise invalids into the wise.

Leaving Nordrach, I proceeded to Davos Platz, ascending 5,000 feet in a few hours. Here I found this beautiful place prosperous, extending itself, and well filled with invalids, considering that it was the summer season. All appearances belied the statements that had been made to me by the enthusiasts of the home open-air sanatorium treatment, viz., that Davos, strangled in its own smoke, crowded with germs, and without the hygienic benefits of sanatorium treatment, was rapidly dying. On the contrary it seemed extremely prosper-

ous, the many excellent hotels were well provided with porches and sun parlors, balconies, and other resources for invalids.

As regards sanatoriums, the valley rejoices in several. There are at present two institutions for the well-to-do, Dr. Turban's and Dr. Philippi's; Dr. Turban's establishment being very complete, and evidently managed with great skill and care. This institution in its methods bears a close resemblance to those of Brehmer at Goerbersdorf and Dettweiler at Falkenstein, the rest-cure being carried on out-of-doors. Careful attention seems to be paid to all concomitant disorders and diseases of the consumptive. The town has grown round the institution, so that the grounds are not as spacious or as open as could be desired. Here the custom is to give six meals a day, while at Nordrach only three regular meals are usually allowed.

For the poor there is the Basel Sanatorium at Davos Dorf under the direction of Dr. Egger. It is an admirable and successful institution. There is also a good sanatorium for the Dutch, and another for the English.

There is now being built a very much finer establishment than any of these for the richer class. It has a very much better situation, being several hundred feet above the valley, upon a small plateau on the slopes of the Schartz Alp. Here purer air and more sunlight with good shelter from the north is procured than in the village. The building when completed will cost \$500,000. I inspected it with much interest with Dr. Neumann, who will be the resident physician; Dr. Spengler being the medical director. It is reached by a funicular railroad. It is solidly built of stone and will be as thoroughly hygienic and as fully equipped as any sanatorium at present existing. My visit to Davos closed my tour of the sanatoria.

When I tried to sort out and arrange my various observations, and to endeavor to find out what was the practical outcome of it all, I found that while I had formed certain definite opinions it was not so easy to furnish valid proofs of my beliefs. In the first place, in considering the merits of the sanatorium treatment, I was confirmed in my previous opinion of its value for a time at least, especially in the earlier stages of the disease, for a large proportion of phthisical patients.

In my work on Medical Climatology, I have given what I believe is good evidence and I will here endeavor to analyze more recent statistics with reference to the same points. The difficulty in making such statistical inquiries is in finding reports that are made out on similar lines so that they may be compared. The work of Dr. F. R. Walters' "Sanatoria for Consumptives" (pages 48 to 57 inclusive), and Dr. S. A. Knopf's book entitled "Pulmonary Tuberculosis" (pages 328 to 330 inclusive), contain summaries of the reports of results from the most important sanatoria up to date. I examined several of the original records, but could find nothing to assist me further in my search after comparative results in closed and open sanatoria in low and high climates.

I have also in the "Handbook of Climatology" given statistical evidence of the relative value of high and low climates in open resorts. What I particularly desire to obtain at the present time is the relative value of sanatoria and open resort treatment in low climates and high climates respectively, and, most of all, the relative value of closed sanatorium treatment carried on in lowland as against highland climates. From the references referred to, I extracted the following tables. The reason

of the statistics taking the form they do, and being limited to only a few of the total number of reports, will be obvious to the reader of the references:

TABLE I.
COMPARATIVE RESULTS IN SANATORIA IN HIGH AND LOW CLIMATES.
COMBINED FIRST AND SECOND-STAGE CASES ONLY.
(Taken from Dr. Walters, pp. 52 and 53.)

1876-1886.	Altitude.	Number of Cases.	Number Benefited.	Per Cent.
LOWLAND CLIMATES.				
Goerbersdorf (Manasse)	1,810 ft.	3,615	1,294	36
Falkenstein (Dettweiler)	1,875 ft.	1,022	746	73
Reiboldsgrün (Driver)	2,300 ft.	2,000	1,400	70
Total		6,637	3,440	Average, 51
HIGHLAND CLIMATES.				
Leysin (Bernier)	4,150 ft.	37	34	92
Davos (Turban)	5,115 ft.	302	269	89
Arosa (Jacobi)	6,000 ft.	259	212	82
Total		598	515	Average, 86

The total average of benefited in low climates was 71%.¹
" " " " " high " " 86%.

¹ Without Goerbersdorf.

The Goerbersdorf reports up to 1884 are so much lower in the percent of benefited to the others—owing, perhaps, to some different method of estimating results, or, perhaps, to their being taken so many years ago, when the material was worse and the treatment perhaps not as efficient—that probably it would bring out the truth better to omit them.

TABLE II.
COMPARATIVE RESULTS IN OPEN RESORTS IN LOW AND HIGH CLIMATES.
(Taken from Handbook, pp. 132 and 133.)

ALL STAGES.				
	Number of Cases.	Number Benefited.	Per Cent.	
LOWLAND CLIMATES.				
Desert Climates	154	100	65	
Island Climates	568	295	52	
Coast Climates	2,328	1,369	59	
Inland Climates	136	77	57	
Total	3,186	1,841	Average, 58	
HIGHLAND CLIMATES.				
Alps (Davos)	2,027	1,551	77	
Colorado	571	420	73	
Total	2,598	1,971	Average, 76	

The total average of benefited—lowland climates, 57%.
" " " " " highland " " 76%.

My first table, Table I, deals with the comparative results in sanatoria in high and low climates, first and second stage cases combined being alone taken, and the different variety of forms of improvement being grouped

under the head of benefited. Of the lowland sanatoria the lowest elevation above sea-level was 1,840 feet, and the highest 3,300 feet. Of the highland climates the lowest elevation was 4,150 feet, and the highest, 6,000 feet. The total average percentage of benefited in low climates was 71, and in high climates 86.

Table II gives comparative results in open resorts in low and high climates. The total average of benefited in lowland climates was 57%, in highland climates 76%.

TABLE III.

COMPARATIVE RESULTS IN HIGH AND LOW CLIMATES IN OPEN AND CLOSED RESORTS.

SANATORIUMS.	Per Cent. Benefited.	OPEN RESORTS.
LOWLAND CLIMATES.		
Hygeia (A. Klobs)	69	
Goerbersdorf (Brehmer)	76	
Adirondack (Trudeau)	77	
Average	74	Average percent. of benefited, 58
HIGHLAND CLIMATES.		
Davos (Turban)		
Arosa (Jacobi)		
Average	84	Average percent. of benefited, 76

Table III shows the comparative results in high and low climates in open and closed resorts. The cases, however, could not be obtained in first and second stage cases alone, but only of all stages combined. In lowland climates the closed sanatoria show 74% benefited, and the open resorts 58% benefited. In highland climates the closed sanatoria show 84% benefited and the open resorts 76%, exhibiting the relative superiority of sanatorium over open resort treatment in the two classes of climates, respectively. Doubtless the sanatorium cases were on the whole in better condition upon first coming under treatment than those in the open resorts and, therefore, the superiority of sanatorium treatment over open methods is probably not as great as it appears here; but, nevertheless, I believe even if the material was exactly the same, the sanatoriums would show a greater percentage of benefited over the open resorts.

Table III also proves that climate exercises a beneficial influence over patients in closed sanatoriums as well as in open resorts. In all stages combined the percentage of benefited in sanatoriums in low climates was 74%, while in high climates it was 84%.

In the first and second stage cases combined (see in Table I), the difference in favor of mountain sanatoria is still greater,—lowland sanatoria 71%; highland sanatoria 86%.

These investigations, I believe therefore, establish the following conclusions: That the sanatorium treatment is a good thing, particularly when patients are kept in the full air, but that it is not quite such a good thing, or as widely applicable, as its advocates believe. It is not the quantity of the air, or the negative virtue of purity, that is alone desirable, but the quality of the air that is also of supreme importance; in other words, climate is of the greatest value, and if you give equally good hygienic conditions to your patient, that patient who is placed in the climate best suited to his needs is

going to improve the quickest, and his disease is more likely to be permanently arrested.

The oft-asserted belief of the advocates of home sanatoriums that a tuberculous patient is best cured in his own climate is, I believe, a fallacy. He is cured as much on the mountain top, the wide plain, or the seashore as those cured at home, and no more and no less. There are certain evident economic reasons why home sanatoriums should be encouraged, up to a certain point. I believe, however, where circumstances permit, it is safer to change the air and locality of the consumptive for a time, and by doing so results are brought about much more rapidly and surely than if he remains at home; but, as I have said elsewhere, "climate without hygiene is but as 'sounding brass and a tinkling cymbal.'"

A CASE OF ACUTE TUBERCULOSIS OF THE MESENTERIC GLANDS OF THE ILEOCECAL COIL; REMOVAL: PERMANENT RECOVERY.¹

By MAURICE H. RICHARDSON, M.D.,
of Boston.

THOUGH the frequency of acute tuberculosis of the mesenteric glands cannot be great, I have met a few cases. In these cases I have found the lymph-glands apparently infected as far as it was deemed advisable to push the exploration. In many instances structures other than the lymph-glands themselves have shown tuberculous lesions. The milary form of tubercular peritonitis, with ascites, shows as a rule no special involvement of the lymph-glands. If enlarged they are not markedly so. Occasionally, however, the lymph-glands show more evidence of infection than the peritoneal areas themselves, parietal and visceral. I have come to regard that form of general tuberculosis in which there is infiltration of the mesenteric glands as more serious than the ascitic form with milary nodules distributed everywhere throughout the peritoneum, for I have operated with most encouraging results in numerous cases of the latter. On the other hand, explorations in which large masses of tubercular deposits have been found here and there in the abdominal cavity have usually been without benefit. In some instances the patients have slowly wasted away; in others fecal fistulas have formed; in still others, however, simple exploration has been followed by that rapid and permanent recovery so hard to explain.

Acute tuberculous affections of the mesenteric glands distinctly localized have been so unusual that I can recall but two cases. One was that of a young colored girl who had a tumor about the size of an orange situated in the region under and a little above the umbilicus. There was moderate constitutional disturbance. Exploration showed a collection of cheesy pus between, and involving, folds of mesentery. Drainage of the collection was followed by temporary improvement. The girl finally died of pulmonary tuberculosis.

Enlargement of the mesenteric glands is by no means infrequently seen in the course of abdominal operations. At operations for chronic appendicitis, I have found the mesentery of the ileocecal coil studded with small, hard glands. Similar enlargements have been demonstrated at operations for other lesions. In some instances the glands are found to be cheesy, or even

¹ Read before the American Surgical Association in Washington, May, 1900.

calcified. In one recent case I found a hard, irregular, and angular tumor, hanging from the mesentery by a small pedicle.

In another case, that of a young woman, the sigmoid flexure contained, at its mesenteric border, a calcified mass about the size of an olive. This lesion was discovered in the course of an operation for chronic appendicitis. It seemed most likely an enlarged gland situated in the mesentery so close to the intestine that it finally involved it, becoming in the course of time calcareous and innocuous. There had never been in previous years any symptoms noticed which this tumor would have explained.

In the case of a man of middle life operated on in the present year, I found a chylous ascites associated with numerous enlarged glands of the mesentery of the small intestine. The lacteals were prominently injected, showing as fine white lines upon an intensely reddened intestine. The diagnosis in this case was uncertain, as no glands were removed; but it seemed not improbable that the lesion was tubercular, the glands being so numerous and so closely matted together as to obstruct the lacteals.

Enlarged glands limited to the mesentery of the ileocecal coil, whether they be regarded as cured or as only quiescent, suggest that the operation—usually performed for a supposed chronic appendicitis—rests upon an incorrect diagnosis; that the attacks of supposed appendicitis might have been attacks of acute localized mesenteric tuberculosis. Nevertheless, in such cases the appendix has shown distinct evidence of disease, and its removal has been followed by recovery thus far permanent. The infectious process in the appendix probably extended to the nearest glands, the operation in the interval exposing them in a condition of quiescence.

The only instance of acute appendicitis associated with a general tuberculosis of the abdominal viscera was that of a young boy operated upon in 1900. There had been a perforation of the appendix with a localized abscess. The peritoneal cavity was filled with disseminated tuberculous masses, the glands of the mesentery suggesting bunches of grapes.

It is by no means impossible that in some cases the infectious process of the appendix is in the first instance tubercular, and that the general dissemination is secondary; or that the infection may have started in the cecum itself, involving later the appendix and the mesenteric glands. I have resected the ileocecal coil several times for tubercular stricture of the intestinal wall. In most of these instances the operation has been performed for a persistent fecal sinus following operation for acute appendicitis. In one case the resection was performed for a stricture of small lumen in the ascending colon. In this case, even, the lesion may have started in the appendix, for the process involved the whole ileocecal coil.

The truth is, probably, that the disease starts as an acute process, and so closely resembles an acute appendicitis that a distinction before operation is impossible. Indeed, at the operation itself the tubercular nature of the infection may not be suspected, the diagnosis being suggested only after prolonged suppuration of the wound, fecal fistula, localized and persistent tumor.

In the case herewith reported, which is the only one of the kind that I have ever seen, the diagnosis of acute appendicitis was made by Dr. Craigin, Dr. Mixter, Dr. Brewster, and myself. The true lesion was never for a moment suspected.

The patient, S. M., was a strong, healthy boy, aged nearly 5. At 11 months he had had the measles. From that time to March, 1895, he was an unusually healthy child. He then had a severe attack of influenza, with double otitis media. By May 1 he had entirely recovered. On June 16, 1895, he was apparently in perfect health. Dr. Craigin's notes are as follows:

June 17 he was out of sorts, was feverish, had colicky pains, and was constipated. The pulse was 140; the respirations, while sleeping, 40. June 18 he had a restless night, with frequent colicky pains. These recurred at times during the day. The pulse dropped from 140 to 120. The temperature was 103.5° in the morning; 103.2° at night. June 19, there had been during the night frequent but transitory pains in the lower abdomen. The bowels were opened freely by means of calomel. The stool contained apple skins. The patient had been overeating before June 18. The morning temperature was 102.6°, the pulse 120. Once in the afternoon he had pain in the lower abdomen and in the right thigh. The evening temperature was 10.42°, pulse 140.

I saw the patient for the first time on the evening of June 19. I found a tender mass in the region of the appendix. Drs. Mixter and Brewster confirmed the existence of this tumor, which we supposed to be an acutely inflamed appendix with adhesions and exudations. Immediate operation was advised and performed.

The incision revealed a healthy cecum and an unaffected appendix. In the mesentery of the ileocecal coil were numerous enlarged glands, varying in size from that of an English walnut to that of a large pea. The largest glands were contiguous to the intestine; toward the receptaculum chyli they diminished rapidly in size. The glands were carefully removed from the mesentery, with as little cutting as possible. The dissection was carried up several inches, until no more affected glands could be found. The appendix was not removed. A small gauze wick was left in the depths of the wound, and the wound itself was partly closed with interrupted silkwormgut sutures.

The operation was borne well. The temperature reached normal on the third day, and convalescence was without special incident. Most of the glands removed were pink and juicy. Among them were two small cheesy ones. The gross appearances were strongly suggestive of an acute tuberculosis, and it was not at all surprising to receive from Dr. Mallory the following note:

"HARVARD MEDICAL SCHOOL, June 23, 1895.

"DEAR SIR: In regard to the lymph-glands removed from Dr. M.'s little boy, I am sorry to have to confirm what must have been your own diagnosis on incising them—tuberculosis."

The disappointment that followed the demonstration of the lesion may be imagined. Instead of a simple appendicitis—bad as that is—there was an acute lesion, which, so far as any of us had known or seen, was absolutely incurable and hopeless, an acute tabes mesenterica, an infiltration of organs and regions so close to the great channels of lymph-absorption and distribution that complete removal seemed impossible. The tone of discouragement so evident in Dr. Mallory's report, though it came when all local and constitutional signs were improving, brings back vividly the feeling of absolute hopelessness as to the ultimate outcome which prevailed in this case.

The improvement of the early hours continued, however, without a single unfavorable sign. No manifestation of local or remote tubercular infection developed. The convalescence was perfect and permanent. The patient, now, is a boy of robust health.

Cases of this kind must be extremely rare. Not that tuberculosis of the abdominal viscera is rare, for, taken as a whole, it is a common disease. Limited, however, to a single small area of the peritoneum or of peritoneum-covered viscera it is extremely unusual; limited to an area that permits complete extirpation it is more unusual still.

The cases diagnosticated as appendicitis with abscess, in which the operation is simple drainage, may in some instances be tubercular in origin. The cases of appendectomy, whether acute or chronic, do not often offer the least suggestion of a tubercular origin. Doubtless many of them are tubercular, as I have already said.

In cases of glandular tuberculosis limited to a single coil it must be assumed that the infection takes place directly through the intestinal wall. Infections beginning thus are likely to be overlooked in the early physical examination, when the patient is perhaps robust and the abdominal walls are thick, unless the inflamed and tender mass is so situated that palpation is possible.

In the case herewith reported the initial symptoms suggested appendicitis; the lesion actually found, though regarded as hopeless, was attacked just as similar lesions in the neck are attacked. The result was just as gratifying.

This case, it seems to me, is one of great value in questions connected with acute abdominal symptoms, and especially with the treatment of suspected abdominal tuberculosis. It is an argument in favor of an early operation when the symptoms are acute and severe, not only when the diagnosis is clear, but more especially when it is obscure.

The results following operations for tuberculosis are often so inexplicable—much good following an operation apparently so incomplete as to be absolutely inadequate—that one is justified in operating, even when it is clear that the dissection can be only partial. The instances of cure are so numerous after simple incisions of tubercular peritonitis, after the removal of a tubercular tube, after the curetting of tubercular fascia—after many operations which remove only part of the disease—that surgical intervention has become, it seems to me, a duty whenever intervention is possible.

In mesenteric tuberculosis, in particular, removal of the affected glands is indicated whenever their removal is technically possible,—that is to say, when the glands are limited to areas easy of exploration, and when they themselves permit easy enucleation.

PERSONAL VIEWS REGARDING THE CLIMATE OF THE ROCKY MOUNTAINS IN THE TREATMENT OF TUBERCULOSIS.

By S. D. VAN METER, M.D.,*
of Denver, Colo.

AFTER several years' residence in the South and East, followed by an experience of ten years' practice in Colorado, during which time I have visited nearly every section of the Rocky Mountains, always studying with deep interest the relative climatic advantages of the different localities, I feel qualified to give a fairly intelligent opinion on the points arising in discussing the relative climatic advantages of the different sections of North America. For practical purposes it could be divided into the East, South, Pacific, and West, the latter to mean that section of country embracing the Rocky Mountains in Wyoming, Colorado, New Mexico, Arizona, Northern and Central Old Mexico. However, it is not the intent of this paper to discuss the advantages or disadvantages of any of these sections, but to presume that it is an accepted fact in the minds of the majority of medical men that the latter, or West, as I have arbi-

trarily designated it, is so superior to all others it is not necessary to further discuss the relative merits of either; and to give my personal views and observations on the subject has been my desire for some time past, but having such a strong belief in the unquestionable superiority of the West, I have been deterred from so doing by the fear of accusation of having an ulterior motive. Several years ago I withdrew from medical practice, and limited my work to surgery, hence at present there is nothing to be feared in that direction, and to further strengthen my position, permit me to state that as far as the possibility of increasing my professional income, I care not if no more tuberculous patients come to Colorado. I am well aware many writers on Western climate have views somewhat different from mine, and some may criticise this paper as being void of scientific research and statistics. However, if I have presumed too much in supposing my personal views will be better received and appreciated than history of cases and tables of temperature and barometric readings, I will abide the consequences.

It may be claimed by some that the great climatic advantages of the West are so well known that it is not justifiable to increase the literature on the subject. Further, that the medical profession appreciate it fully, and are thoroughly posted as to how, when and where patients should be sent. Many of the profession fortunately do, but many, many more do not. Pardon my saying that the inexcusable ignorance of this subject that is displayed by a great number of the profession, in the erroneous and inconsistent directions and advice given to the patients they send to this climate, is so palpably absurd, that such alone warrants the conclusion, *much education along this line is greatly needed*. By way of excuse it may be said, it is impossible to obtain anything approaching a clear conception of the peculiar surroundings, climatic and other conditions of any section of the world, without a personal visit. Hence a summer's outing in the Rockies for every medical man who has not had that pleasure is recommended as the thing, par excellence, to eradicate erroneous impressions. He may be assured a most delightful vacation, as well as clearer ideas upon all of the many points in question than he can ever expect to have from study of the existing or coming literature.

The question is often asked, what section of the Rocky Mountains is the best. At present there is no best. The numerous points to decide, that vary in every case of consumption, unfortunately necessitate that each should be considered by itself; in the end choosing that place most suitable to the circumstances and peculiarities of the patient. The perfect and the ideal are difficult to obtain when cost is not to be considered. Unfortunately, the majority of invalids are not blessed with wealth, and the consumptive seeking the best of climate and accommodations needs to be well supplied with money.

From purely a climatic point of view that portion of Central and Northern Old Mexico traversed by the Sierra Madres offers the best all-the-year-round climate of the whole West. It combines the requisites of proper elevation, equable temperature, minimum atmospheric humidity, freedom from snow, a small annual rainfall, and, last but not least, comparative freedom from wind and dust storms. However, there are two serious objections to this section. They are the absence of accommodations, and the fact that but little English is spoken. The latter can, of course, be easily overcome, but the

*Owing to unavoidable circumstances, publication of this article has been deferred an unusually long time — [ED. PHILADELPHIA MEDICAL JOURNAL.]

first is difficult, in fact so much so that only those well supplied with money can overcome it, by having their own cooks, provisions, bedding, and general living and camping outfits. I may convey the wrong impression in using the phrase *absence of accommodations*. There are good accommodations to be had in the large cities, but, on the whole, they are poor as compared with those the average well American wants, and the invalid seeking health, will not think my use of the word "absence" too strong. Personally, I am used to, and very fond of *frijoles*, *chili-con-carne*, and other Mexican dishes, but more than once, after a sojourn of several weeks in Old Mexico, the viands set before me at the first Harvey eating house, after reaching the United States, looked and tasted like food "fit for the gods." This serious objection keeps numerous consumptives from going to

these territories to the northern, along the Colorado State line, the country becomes more mountainous, with increase of altitude, lower mean temperature, and heavier fall of snow, but there are less wind and dust storms. Accommodations too are better, and I know of no finer section for camping and out-of-door life, which can be enjoyed the greater part, if not the whole, of the year.

Leaving this section and coming north into Central and Northern Colorado, a very grand and beautiful section of the Rocky Mountains is reached. To it may be added Southern Wyoming and Idaho, as this area of mountain parks and rock-ribbed canons does not stop suddenly at the Colorado State line. Naturally there is considerable difference as to the commencement of spring and fall in the extreme north and south of this

section, but good accommodations are to be had; and for seven months of the year the climate, *although far from perfect*, on the whole, is all that can be expected. The numerous hotels and ranches in the canons leading east and west from the main range, together with those located in the natural parks, chief of which are Middle, North, Estes, and South Park, offer homes approaching the ideal for consumptives during spring, summer, and fall, but the cold winter and wet snows of February and early March constitute objections that prevent an honest observer claiming for this section an ideal all-the-year-round climate. True, many incipient cases do well here all through the winter, but the chances are, *they would have done better had they gone South*. Like all elevated mountainous regions in this latitude, where 13,000 to 14,000 feet means perpetual snow, the great difference between day and night temperature, and the sudden change at sunset, are noticeable characteristics and features all newcomers should know, that they may avoid bad results therefrom. The sun a half hour before sinking behind the western horizon may be so intense as to blister the skin,

this section. Time and the rapidly-increasing American emigration to Mexico will bring about a correction, and I prophesy that the day is not far in the future when Old Mexico will be the most popular climate on this continent for tuberculous patients.

Coming north into New Mexico and Arizona conditions change somewhat, for better and worse in some of the requisites of an ideal climate. Here there is some snow, although in most localities of this section it is of short duration. The wind and alkali dust storms become serious objections at certain seasons. Accommodations, while not perfect, are fair, and each year brings decided improvement. The proper altitude, dryness, and predominance of sunny days over the cloudy, are features to which this section can well lay claim. Mining and ranching are the chief industries, although farming by irrigation is successfully carried on, but the first-mentioned industries overshadow it.

Passing from the southern and middle portions of

and a few minutes later an overcoat will be comfortable. The use of light-weight pure wool underwear for the summer months is to be strongly recommended. The scenic photographer has of late years made these canons and parks well known in the picture world, but to appreciate their full grandeur, cool atmosphere, pure mountain water, the beautiful streams which abound in the angler's delight, the wily trout, one has to see, breathe, and taste for himself. As the hotels of the eastern side of the main range are left behind, and you pass to the north and west, the country becomes less populous, being farther removed from railroad centers. This renders that part of the section less accessible, and acts as a practical quarantine against the majority of advanced pulmonary cases. However, to those who are well enough to get away from civilization, who wish to live in the open air, camp out, hunt and fish, they can find a no more delightful country in which to satisfy their desires. They will find plenty of deer, antelope

and grouse, some bear and elk, beside the many wild animals unfit for food, such as the panther, wild cat, and coyote. The streams not only abound in fish, but they can be caught by other than an expert angler. This being a general outline of the different sections of the West, from my personal observation and experience, it is but natural that my conclusion is that, to secure the best climate at present, a tuberculous patient must be financially able to spend from May to October in the last-named section, October and November in southern Colorado and northern New Mexico; December, January, February, and March in southern New Mexico, Arizona, or Old Mexico, returning North in April, to repeat the migration with the seasons. This plan is expensive, as distances are greater than most Eastern people think, and cannot be considered feasible by any one of limited means, unless he take up the major part of the time going and coming in a camp wagon. This method becomes monotonous to the majority, but has its advantages of insuring constant out-door life and keeping patients away from the danger of civilized life, society and its health-sacrificing requirements. It must be admitted that the evil of intemperance exists to no small degree at most resorts in the West. When I say intemperance I do not mean in the excessive use of alcoholics alone, but in its broadest sense. The fact that alcohol judiciously used is useful as a drug in the treatment of tuberculosis paves the way and stands as an excuse for a great number of invalids' intemperate use thereof. Being freed from the restraining influence of family ties and the moral example of a large home acquaintance, and finding many others of the same social position who pass unnoticed acts that would set their home circle agog, with ample and frequent opportunities and temptations, the average consumptive seeking health in the West, with human appetites, cannot be expected to do other than frequently indulge intemperately, especially when physical infirmities necessitate more or less idleness.

One of the most common histories given by the consumptive seeking medical advice in Colorado is as follows: "About a year ago I had the grip and it left me with a cough. I kept running down and my doctor told me I had better try Colorado climate. To come to Denver, throw all medicine away, live in the open air, and let the doctors alone." The ridiculousness of such advice is so self-evident it may seem needless to dwell on any discussion to demonstrate error and inconsistency. However, it is so common, and illustrates several vital points of the erroneous ideas of the East concerning the West, I must call attention to such errors. Nine chances out of ten the patient was infected with the tubercle-bacillus near the date of the attack of the grip, and the attending physician should have been able to detect the physical signs thereof long before the date of recommending Colorado climate. Furthermore, Denver, the Mecca of the West for consumptives, is no longer the place in Colorado to send patients afflicted with tuberculosis, if circumstances permit their being sent elsewhere. True, as compared with cities in the East of like population, it is far ahead, but with its dust, smoke, and smelter fumes laden with lead, arsenic, and sulphur, no one should think of Denver as the place in Colorado or the West to send consumptives. Patients should be instructed to go to the rural mountain districts, and strongly impressed with the fact that none of the cities or larger towns represent western climate. The smoke and smelter fumes in cities like Denver, a mile

above sea level, are much more objectionable than they would be in a lower and more humid atmosphere. Here, owing to the dryness of the air, the smoke and fumes from furnaces do not rise, but settle down like a mantle over the city, and the small particles of dust float in the atmosphere much longer than they would where increased humidity, and consequent absorption of moisture, would cause their precipitation to the ground. It is true there are cases of incipient tuberculosis who, from necessity of earning their daily bread through an occupation, only to be followed in a city, are compelled to reside in one of these cities when they seek the climate of the West. But these should be told the advantages of suburban residence which, fortunately, while somewhat inconvenient, is cheaper than that of a more central location. At best, however, it is but a compromise.

At no time does the consumptive need the counsel of a physician more than immediately after arrival. The many changed conditions consequent upon the great increase in altitude alone justify the early consultation of a local physician. Ignorance of such conditions often results in the *tenderfoot* consumptive doing himself irremediable harm, which might be easily avoided by timely advice. Chief of these is a great stimulating effect upon the whole system, often causing the patient to almost forget he is ill, and to attempt physical efforts unwise for a well person. Consumptives on arrival in this climate should exert themselves very little, increasing physical exercise with care, never pushing it to the point of fatigue. I have seen several cases of pneumothorax in cases of limited area of pulmonary involvement, coming on during the first week after arrival in Denver. Possibly the same might have developed elsewhere, but in my opinion the chief factor in their production was unnecessary physical effort, which in turn, owing to the rarefied air and the consequent necessity of bringing all residual lung-space into use to secure sufficient oxygen, produced an excessive strain on a weak spot in the tuberculous area, which should have been avoided. There are other points of information, such as the water-supplies of the different localities, the absence or existence of this or that objection, etc., in certain sections, that the consumptive can obtain by consulting a physician on arrival in the West, that such a course cannot be too strongly recommended. Many serious mistakes could have been avoided in the past, and may be in the future by its adoption.

Having little faith in the drug treatment of tuberculosis, I can in a measure agree with the oft-repeated instruction of throwing all medicine away. I have yet to see the direct curative effect of any drug in constitutional tuberculosis, and believe that pure air, the direct rays of the sun, pure nourishing food, an altitude from 4,000 to 8,000 feet, and careful hygienic regimen constitute the major part of the logical treatment of this dread disease, as we know it today. However, it is by no means my idea to decry the use, the judicious use of drugs. The tonics especially have done too much good in tuberculosis for us to forget or disregard their administration. In the despondent class they serve as a something material upon which to build a hope of recovery, a *sine qua non* in that class of cases which is extremely large in Colorado, where so many suffer from homesickness. A careful consideration of the possible development of this distressing condition should never be forgotten when a patient is contemplating coming to this section in search of health. Many of our numerous

suicides are found to be amongst homesick consumptives.

The cases that do best are naturally the incipient with good family history. All of these do not have the pathologic process completely arrested, but the large majority are benefited, and many cured. My idea of a cure of the disease is a complete arrest of the pathologic process. Further than hoping to prolong life, it is useless to send advanced cases West. It is worse than criminal to allow, much less advise, such cases to spend their all in so futile and expensive a journey. They come here to die, and increase the death-rate of the State, and injure the reputation of our climate. All of this the section can well stand, but when it means the last dollar to the patient, and perhaps his family also, it should be decried. Better far use that money in procuring those comforts it will buy at home to mellow the sufferings of approaching death. Often have I seen patients cooped up in cramped, uncomfortable lodgings, living on poor food, poorly prepared, who had been accustomed to all the freedom of a good Eastern home, with its abundant food of better quality than the average Western hotel. Poor, deluded victims! They felt they were getting the full benefit of Rocky Mountain climate. The incipient cases of limited means may do well by seeking employment, especially in the rural mountain districts, but those requiring the attention of another person had better be kept at home. It can be well said the advanced cases of consumption patronize the Pullman Car Company when coming west, but they go back via the Adams Express, *two tickets for one*.

In this era when the contagiousness of tuberculosis is so much discussed, it is no wonder people who do not understand the disease advocate legislation whereby this immigration of consumptives can be stopped. The unnecessary sending of advanced cases has done more to awaken this feeling than anything else. The great number that become charges in the public hospitals soon after their arrival, cannot have any other effect but to make those in charge feel something should be done to lessen or check an unjust burden. Several Boards of Trade have absolutely refused to insert paragraphs in their advertising literature describing the climatic advantages of Colorado in pulmonary diseases, feeling they would be encouraging a class of immigration detrimental to the State. This sentiment would never have developed had not that large annual number of hopelessly far advanced cases been literally sent to this section to die. In California one of the medical societies has gone so far as to pass a resolution appointing a committee to consider the advisability of some quarantine legislation against advanced cases. The medical men who are behind that resolution, more than likely feel the numerous pleadings of the resident profession to their Eastern brethren have been so wholly ignored that further effort in that direction is worse than useless. There is no danger of any legislation of this nature being passed by any of the Western legislatures, but the agitation should bring the fact forcibly to view that a medical man is doing a great wrong to patients and to the West to allow, much less advise, the coming to this section of advanced tuberculous cases.

The cases that do the very best among the incipient class of good family history are those who live the greater part of the year in camp, and out-door life, who follow out-door occupations after the arrest of tuberculous process; and, last but not less important, those who do not tempt Nature by leaving this climate, even for short

trips East. This question comes up so frequently, and after reconsidering it many times, I cannot too strongly recommend that all consumptives who come to the Rocky Mountains and are fortunate in securing relief, should "*burn their bridges behind them*." It stands to reason that the climate where a pathologic process developed in previously healthy tissue will more than probably fan a smouldering fire into new activity, too often to a flaming point beyond checking with any means known to mortal man. Three out of every five consumptives who come to the Rockies, labor under the impression they will get well in six months to a year, when they will be at perfect liberty to return to their former homes, take up their former occupations, and look upon their experience in the West to rid themselves of tuberculosis as they would a course of quinin for the eradication of malaria. Such impressions no doubt chiefly arise from that peculiar hopefulness so common in the disease, but in part is due to misinformation given by the physician fearing to tell the truth lest the patient shall not undertake the change. It may be the right thing to keep back the whole truth at times, when circumstances are extenuating, but to mislead patients into the idea of rapid recovery in so chronic a disease cannot be upheld as justifiable. On the other hand it is to be branded as unjust, and unbecoming the honor of a physician.

The good effect of this climate in laryngeal tuberculosis is demonstrated in the slow progress of the disease in the untreated cases, and the better response to treatment. I have not had the opportunity of seeing cases of this class treated at a lower altitude since formaldehyd has come into use, but it is my opinion, all things being equal, these cases do better here than in the East. The results I have seen in the hands of several of our local laryngologists have been flattering as compared with the results observed in Philadelphia under former treatment of lactic acid, etc., which usually was a steady downward progress and rapid ending of a life of suffering, torture, and agony.

While speaking of laryngeal consumption, I cannot refrain from referring to a statement made by Dr. Howard S. Anders, in an article entitled "A Visit to the Loomis Sanitarium for Consumptives," published in the August, 1899, *University of Pennsylvania Medical Magazine*, wherein he states that "nearly 50% of the cases of tuberculous ulceration of the throat have been cured—a much better showing than at the various health-resorts in Colorado." Had I not been a college-mate and hospital-chum of the doctor, and known so well his strict temperance views on the use of alcoholics, my natural conclusions would have been that the Board of Control of the Loomis Sanitarium probably got him into a peculiar condition of diplopia, with a degree of blurring in outline, and in such condition he mistook the figure 5 for 50, which would be nearer correct. After seeing figures this way, he was perfectly justified in his conclusions relative to the results obtained at the various health-resorts of Colorado. None half so encouraging have ever been claimed. It is to be hoped Dr. Anders is correct in his statement, but how he can be seems impossible. It is difficult to believe, when the most hopeful enthusiast must admit that 80% to 85% of all persons infected with the *Bacillus tuberculosis* sooner or later die of that disease. Further, it is well known that the throat cases, as a rule, are those apparently saturated with the infection, show little or no power of resistance, and too often the local manifestation is but

the signal or forerunner of a general infection or breakdown of the patient's constitution. Primary laryngeal tuberculosis is a possibility, but I have never seen it. If it exists, its rarity excludes its consideration for all practical purposes. Local treatment will frequently heal the ulceration perfectly, which means a temporary cure, at least; but the rule is to secure a palliation of pain and hold the pathologic process in check; this is all that can be expected. It is not my intention to cast any reflection on the Loomis Sanitarium, but such statements are too flagrant to pass unnoticed.

In conclusion, allow me to recapitulate and to call attention to the following: Recognize your tuberculous cases early, and lose no time in sending those patients whom you think will do well. Consider all features of the social, financial and physical conditions, not forgetting in any case to carefully judge the probable effect on the individual of a change of residence to a country very different from that to which he has been accustomed. Remember the West offers a salubrious, grand and glorious climate, but by *no means* free from objections. Keep all advanced cases from the undertaking of "trying Colorado climate," unless they are told they can expect nothing but prolongation of life at best, and that it means great increase of expenses. Instruct your patients to call on some local medical man upon arrival. We have plenty of good men, and if you are not acquainted with any, lose no time in putting yourself in possession of information which will enable you to refer your cases to competent men on their arrival in the West. Remember Colorado, with its next-to-worthless and uninforced medical law, is a haven for quacks, and many dollars annually go to them from anxious, uninitiated, *eager-to-try-anything-that-promises-a-cure* consumptives, who, perhaps, need a little honest, wholesome medical advice, and a great deal of nutritious, wholesome food.

To those physicians who have not visited the West and are interested in this subject, a cordial invitation is extended, on behalf of the section at large, to spend your coming summer's vacation with us. You will be assured of a good time, and on your departure will have a better idea of the climate, country, and conditions in general, than is possible without personal observation.

ON THE TREATMENT OF TUBERCULOSIS BY SODIUM CINNAMATE.*

By ALFRED MANN, M.D.,
of Denver, Colo.

Instructor in Medicine in the Deaver College of Medicine of the
University of Denver.

Up to the present time there has been brought forward no specific for the treatment of tuberculosis sufficiently successful to command the general approval of medical men. Hopes of the discovery of such an agent have been widely entertained, only to be given up after long and earnest trials.

Of these numerous disappointments many are due to the circumstance that two very important facts are lost sight of, and both of these are connected with the nature of the disease under consideration.

First and foremost is the character of tuberculosis as a disease which actually *destroys* the tissues it involves. In ordinary croupous pneumonia the lung while inflamed is filled up with products of inflammation and

the portion of lung thus affected is for the time useless for purposes of respiration. But after the process is over resolution sets in, the exudate is liquefied and removed and the lung is as good as before it became inflamed. Diphtheria, like many others of the acute infectious diseases, causes, as a rule, comparatively slight anatomic changes, but is dangerous chiefly through its toxic effects, and the complications to which it opens the door. In pulmonary consumption, on the other hand, in addition to the necrotic changes so characteristic of the action of the tubercle bacillus, there is an inflammatory reaction of the fixed elements of the tissue, and this results in the formation of new connective tissue. It is true this is a conservative process, tending to limit the development of areas of infection. Nevertheless this permanent cicatricial tissue interferes with or actually destroys the functional efficacy of the portion of the lung in which it exists. Thus it becomes largely a question of the extent of the disease process with its inevitable destruction of tissues and of the fibroid changes necessary for healing which determines in any particular case the probability of recovery with sufficient lung tissue remaining functionally efficient to sustain life. Furthermore, it must be remembered that fibroid changes once started tend to advance into unaffected parts of the lungs and so gradually reduce still further the available healthy lung area.

This reasoning takes away the basis for the hope entertained by some that a means will be found to cure even the most advanced cases.

The second circumstance that seems to me to be responsible for many disappointments is that an incorrect analogy is drawn between tuberculosis and certain other infectious diseases, for instance, diphtheria and pneumonia. It is argued that if the animal system reacts to these diseases by producing antitoxins capable of neutralizing their toxic effects, and which can be recovered in the serum of affected animals and used to immunize or cure other individuals, the same must be true of tuberculosis. But the analogy is not a very strong one. It is probable that the antitoxins which appear in the blood as a result of the reaction of the organism to the irritation of the toxins of diphtheria and pneumonia, for example, and the immunoproteidins of Emmerich and Loew in certain other cases, are the agents which bring it about that so many of the acute infectious diseases are characterized by a marked tendency toward a definite critically limited course. The so-called immunoproteidins of Emmerich and Loew, according to these authors, are combinations of bacteriolytic enzymes produced by the bacteria themselves with proteids furnished by the blood or organs of the subject of infection, and effect the cure of the infectious diseases and produce immunity by the actual destruction of the specific bacteria. Thus the immunity conferred by an attack of an infectious disease is the result of a specific reaction of the organism to the disease, or of products of the activity of the bacteria themselves, and it is by means of this immunity, whatever the physiologic character of its mechanism, aided by the nonspecific action of the alexins of Buechner and of the phagocytes of Metschnikow, that the organism is enabled to overcome the disease.

If there is a similar immunizing product of the bacillus and reaction of the organism in the case of tuberculosis, it is certainly nothing like as marked as in the examples quoted above; hence the character of the former as a disease which tends to continue indefinitely and to follow a chronic course.

* Read at the annual meeting of the Colorado State Medical Society, Denver, Colo., June 19, 1900.

We have then two important characteristics in which tuberculosis differs from the acute infectious diseases mentioned above; first, it tends to the production of marked and permanent anatomic changes in the organs and tissues involved, and, second, it causes little or no immunizing reaction in the organism.

The observation that microorganisms often produce substances which, when sufficiently concentrated, interfere with their own development, may yet be turned to account in the treatment of tuberculosis, but up to the present time there is no convincing evidence that an efficient means of treating the disease has been found in this direction. Efforts should not on that account be given up, as a more minute study of the very complex compounds existing in tuberculin may lead to better results than have been achieved in the past.

That there is a strong tendency to spontaneous recovery from tuberculosis is shown by the numerous cases of healed tubercular lesions found in the lungs of persons who have died of other diseases. Furthermore, many cases of tubercular disease of other organs—notably lymph-glands and bones—recover under very simple treatment. The most successful modes of treatment in the past, if we exclude surgical measures, have been those that aimed to improve in every way the general health of the system, those that relied upon the natural tendency of the body to resist and expel infection, and that in any way, directly or indirectly, increased its defensive powers. Among these are first and foremost the out-door and climatic treatment, the dietetic and hygienic methods and the treatment in sanatoria.

Besides these general methods there have been proposed numerous remedies supposed to act in one or another definite or indefinite way to attain the same object.

Among the suggested remedies I have selected one in particular for consideration today, the sodium cinnamate (or *hetol*, as he calls it) recommended by Professor Albert Landerer, of Stuttgart, Germany. This author claims in a series of publications on the subject, the first of which appeared in 1888, to have secured improvement in very many cases, and in a large proportion even complete cures. He has published in detail from time to time the histories and results of many hundred cases of surgical and pulmonary tuberculosis treated by his method of intravenous injection of sodium cinnamate solution, including about 150 pulmonary cases. A number of others have published results of the use of the same method, most of the writers being apparently favorably impressed with them.

Unfortunately there have been, with the exception of Landerer's own statistics, no large series of cases published. In presenting the results of my own short series, I wish it to be understood that it will not bear comparison with statistics of cases as ordinarily published. My cases were specially selected with reference to certain criteria which, though permitting to some extent a judgment in regard to the nature and extent of the effects of Landerer's treatment, would permit but an unfair estimate of its effects if judged only by results without regard to the class of patients reported upon.

There were two kinds of cases selected for this treatment. First, those with lesions so far advanced and so widely extended, or with such other unfavorable conditions, that a good result seemed either very doubtful or well-nigh impossible; and, second,

lighter cases in which for any reason it was thought necessary to make as rapid progress as possible in a comparatively short time. The first group naturally is the most numerous and yielded by far the poorest results, though rightly interpreted, some of these results are very encouraging. The reason for treating light or early cases by this method was usually the expected early return of the patients to the unfavorable climate in which the disease was contracted; for, as a rule, under favorable circumstances, such cases do very well in this climate under proper direction, and it is not by any means in all cases that I recommend the use of sodium cinnamate. My cases number altogether 15. One of these was a man with generalized surgical tuberculosis, in whom the primary focus was in the urogenital apparatus, which was extensively involved and complicated with several suppurating sinuses. This case had secondary foci in the skin of the buttocks, in the sternum and clavicle, and in both lungs and finally died of tubercular meningitis. The prognosis was absolutely bad when he first came to me.

The remaining 14 cases are all pulmonary and none were under treatment less than 2 months; some of the severe cases are still under treatment. All but 2, those classed as light, had daily fever. Four of the 14 were cases that from the extent and severity of the disease and the presence of large cavities bore a bad prognosis. Yet of these, 1 with widespread disease in both lungs and large cavities improved so markedly under the small doses he was able to bear, that in two months he looked like a different being. He had put on flesh, his face was fuller, the gray cachectic look had given place to a healthier rosy color, and his cough and expectoration were very much diminished. This man, who only dragged himself about wearily a few steps at a time before the treatment began, at the end of 2 months, in spite of my directions, took long walks and rode horseback without fatigue. Repeated examination of the lungs showed marked improvement in the physical signs. At this time, for reasons of no consequence in this connection, the treatment was stopped. He continued to feel well for about a month, all the other conditions of his life remaining the same. Then he began to run down; cough, expectoration and fever grew worse, and he rapidly deteriorated until in four or five months he died, with very large cavities in both lungs.

Whether arrest of the disease might have been secured in this case by continued treatment, it is impossible to say, certainly the marked and steady improvement seemed to be due to the sodium cinnamate and did not continue after the influence of this drug stopped, although climate and mode of life remained the same.

In the other 3 cases of the group classed as hopeless the treatment was instituted merely as a forlorn hope in the late stages and apparently only slightly affected the course of the disease, if at all.

Of the 2 light cases the first was a very early one with no physical signs but a single click in the left apex, but with plenty of bacilli in the sputum. Under this treatment the sputum rapidly diminished in quantity. An intercurrent attack of influenza caused it to increase again, and though smaller in quantity it still contained bacilli when the patient left for the East after receiving 37 injections in 3 months. The weight increased 7 pounds in the first 9 days, and before he left he had gained 27 pounds, weighing 7 pounds more than ever before. Now, 14 months later, this patient, a dentist, reports that in the course of a few weeks after cessation

of the treatment the slight remaining expectoration ceased entirely. He returned to his former place of residence and has been working hard at his profession ever since without a sign of returning trouble, even holding his weight.

The other case classed as light was placed in this group in spite of the fact that there was disease in both lungs, slight infiltration in the left apex, but dulness to the lower border of the third rib on the right side, with altered breath-sounds some distance below this. In spite of a duration of over a year and a half the disease in the lungs seemed to be stationary and the general health very fair. Fifty injections given in 3½ months improved all the symptoms so rapidly and to such a degree that nothing was left but a dull area in the right apex; cough and expectoration had disappeared. At this time the patient returned East, looking very much improved, practically well, weighing 115 pounds, a gain of 10 pounds, and 3 pounds more than the highest she had ever weighed when well.

In the group I have called severe cases there are several instances which seem to show that the cinnamic acid has a very powerful healing influence, and others in which it is impossible to say whether any effect was produced or not. Of this class there are 8 cases.

The first is a man who came to Denver with well-marked trouble in June, 1892. After alternating periods of improvement and deterioration, with on the whole a downward course, he began in February, 1894, a series of recrudescences with fever, pleurisy, etc., that occupied the next 7 months. During this time there were 2 copious hemorrhages besides numerous smaller ones. Early in the fall there was an attack of acute pleurisy lasting 2 to 3 weeks.

Out-door life was persisted in for 3 or 4 months and slow improvement was noted. At this time the left lung showed dulness down to the fourth rib and the right to the second rib, there were numerous moist rales over nearly all of the left lung and the larger part of the right. Signs of cavities were detected. There was marked dyspnea on exertion. The expectorate was practically pure pus and was loaded with tubercle-bacilli, though the general condition was decidedly better than it had been 3 months previously. The prognosis, according to 2 well-known Denver physicians, was unfavorable.

At this time, early in February, 1895, intravenous injections of sodium cinnamate were begun. In the first 4 weeks of the treatment the expectoration became mucopurulent, and at the end of 4 months great progress had been made, the expectoration containing only a trace of pus and the area occupied by the rales being very markedly less than before. The patient then went one month without injections, and during this time the improvement was very noticeable. He was then given another series of injections for 3 months, then a rest of 6 weeks, followed by injections for 3 months more. The improvement was continuous. By this time his general health was good. There was slight dulness at the right apex, dulness over the left apex, and dry rales and creaking sounds over the upper lobe. There was then no dyspnea. Bacilli had gradually disappeared from the sputum and have not been found since. There has been no return of the trouble up to the present time, although 4 years have elapsed since the cessation of treatment. The patient still resides in Denver.

The second in the group of severe cases was a young woman who, when 17 years old, had had a slight infil-

tration at one apex, but who was cured by prolonged residence in the South. Several years later, after the birth of her second child, she had a renewal of trouble. Both apices were involved and in addition small areas of infection, probably peribronchial, were detected scattered over nearly the whole right and the larger part of the left lung. Dr. E. G. Janeway, of New York, gave a bad prognosis. In passing, I wish to mention the fact that in this case there was neither cough nor expectoration for 2 or 3 years after the illness began. Finally there was a very slight cough with minimal amounts of sputum which, however, contained tubercle-bacilli.

Residence in the mountains of Arizona for 2½ years under very favorable circumstances had prevented the condition from growing worse, but had not effected any material improvement. There was a daily rise of temperature to from 99.5° to 100° F.

Eight months of injections resulted in cicatrization of all the areas. Improvement was noted after 5 weeks of treatment. At present, 4½ years after cessation of treatment, the patient is apparently as well and strong as ever in her life, only dulness on percussion and bronchial breathing indicating the location of the scars of the former trouble.

Case 3, a woman, 26 years old, is very similar to the last except that the condition was not so widespread but more active and with a higher range of temperature. This patient bore only small doses of the drug, but was improving, contrary to expectation, very nicely, when a visit home, followed by permanent removal to a very favorable location in Old Mexico, stopped all progress, and she finally, after about a year and a half, died. The duration of her treatment by sodium cinnamate was only 2 months, yet the improvement was so marked and so constant that I felt sure of an ultimate good result, when homesickness and financial considerations interfered and stopped the cure so well begun. Her color and general appearance as well as strength had improved considerably.

The next case is a man, 34 years old, small and slender, with a very nervous, excitable disposition and a poor digestion. The area of involvement in the right lung extends down to the fourth rib in front and to 1½ inches above the inferior angle of the scapula behind. The apex of the left lung is also affected down to the second rib. Bronchial breathing in apices, numerous moist rales in diseased areas as above, dulness marked. Had occasional slight hemorrhages. Eighty-five intravenous injections have resulted in better color and considerable general improvement, though being compelled to earn his living interferes considerably with the regularity of treatment as well as its effect. Patient is not cured, but is as well as he ever was, so far as his sensations go, and weighs as much as he ever has done. He still has bacilli in his expectoration, though the latter is very much diminished.

The fifth case of this group is a young woman with widespread and active disease in both lungs, who was improving steadily and gaining weight under this treatment, when it became necessary for her to earn her own living. The bad effect of this work and two or three severe colds, due to exposure, have neutralized the gain, and she is now gradually running down. She had but 39 injections.

The remaining 3 severe cases have received 51, 56, and 94 injections respectively. The first is a bad case in a young man with the whole right lung invaded. He is compelled to earn his living, and from time to time

throughout his illness has had slight and occasionally larger hemorrhages, necessitating interruptions of the treatment. The frequency of the hemoptyses does not seem to be greater than before the use of the hetol. He has improved considerably in strength and general health, and stops work only when he has a hemorrhage.

The next is a case that first attracted attention by causing a very copious hemorrhage. A visit to the East stopped progress, which had begun very nicely with a gain of 16 pounds in a month. Just as improvement was beginning, after his Eastern trip, financial trouble was followed by a second trip East, where the patient now is. It is doubtful if he can pull up a third time. He has had altogether 56 injections, with several long pauses.

The last case of this group is a tall young woman with a weak heart, and both lungs are widely involved. She has had 94 injections, with some improvement, though not a marked advance, during about 9 months.

In 5 of these 8 severe cases worry about financial affairs or the strain incident to earning a living have been and are retarding factors of such moment that, in my judgment, they are almost entirely responsible for the very slow and halting improvement. Six of the 8 cases would ordinarily have been accorded a very doubtful or bad prognosis.

In reviewing my results, it is apparent that the cases are not all affected alike by the treatment. Some very severe cases are rapidly improved; others, apparently no worse, fail to derive any benefit, or do so only slowly. Landerer himself, although he definitely and repeatedly disclaims any specific action for the drug, is of the opinion that purely tubercular infections are the only ones directly acted upon. With the material at my command, I have been unable to arrive at a conclusion on this point; but so far as my facts go they tend, on the whole, to confirm Landerer's position.

As intimated above, the criticism of results reached by any special mode of treatment in the climate of Colorado, so favorable to tubercular cases, is subject to considerable difficulties. Not only the climate enters into the problem, but I have not hesitated in my cases to make use of any of the well-known symptomatic and other remedies that seemed indicated. Along with the hetol I have used tonics freely, such as iron, arsenic, and strychnin, as well as expectorants, and even creosote. Thus it is impossible to exclude the subjective element in the criticism of results. It is matter of judgment, the result largely of experience, to estimate the probable course in any given case, and the extent to which this has been changed by any particular treatment.

Of the worst class of cases 1 out of the 4 apparently received so much benefit from the injections, that a very favorable opinion of the action of the drug is justified.

Of the 8 cases classed as severe the result has been a lasting cure in 2, marked improvement in 3, of whom 1 died a year and a half after the treatment was stopped, and doubtful effects in the remaining 3. I repeat that results in 5 of these cases would in all probability have been much better could the patients have been free from care and worry. In passing I wish to point out that this indicates one of the reasons for the excellent results of treatment in sanatoria. Furthermore, treatment in 2 of these cases was stopped when improvement was rapidly going on, and both patients left Denver and did badly, one in a good location in Old Mexico, the other in Pennsylvania.

The treatment I have used in these cases, and am still using, consists of the intravenous injection of solutions of sodium cinnamate, or hetol, as it is called, and I have followed very closely in all details the directions given by Professor Landerer.

Beginning with $\frac{1}{100}$ to $\frac{1}{50}$ of a grain the dose is gradually increased to $\frac{1}{4}$ or $\frac{1}{3}$ of a grain, which should rarely be exceeded. The injections are repeated every other day. It is very important to use only perfectly pure preparations, such as are made synthetically by certain German chemical houses.

The technic of the injections is very simple, the main point being to secure perfect asepsis. The hands of the operator, the skin about the point of injection, and the instruments should all be carefully sterilized. Usually the median basilic or cephalic vein in one or the other arm is selected for the operation. By encircling the arm some distance above the elbow by an elastic bandage, the vein is rendered prominent and its walls become tense. The needle is then plunged slantingly through the skin and wall of the vein at once. If immediately after the injection and before withdrawing the needle the bandage is loosened and the arm raised up, there is not a drop of blood, as a rule, when the needle is drawn out. The skin about the point of injection is rubbed with ether, then with alcohol. The needle, the point of which should be fine and kept well polished, and which ought to be used for no other purpose, is placed in strong alcohol for 20 minutes before and after using, and the same liquid should be forced through it. Boiling can then be dispensed with, which is an advantage, as it corrodes the point and causes it to pass through the tissues less easily. I have made use of this technic in over 800 injections and have never had the slightest local infection. Indeed, in one of my cases, over 100 injections were made in a single spot less than half an inch square, without a trace of visible effect remaining. An aseptic dressing should be kept over the site of the puncture for a few hours.

The duration of treatment naturally varies considerably. Light cases and those with a purely tubercular infection require a very much shorter period of treatment and furnish a much larger proportion of favorable results than patients with widespread disease, fever, cavities and multiple infections.

I have excluded from this report all cases in which treatment extended over less than two months. The number of injections varied from 25 in two months to 108 in a little over a year. Undoubtedly this treatment would yield much better results if it could be administered to patients living under the careful regime of a well-conducted sanatorium with facilities for the strict carrying out of the rest and out-door plan of treatment. Such an institution is the sanatorium Krühenbad in the Black Forest, directed by Professor Landerer, and remarkable results are reported in the treatment of tuberculous cases.

The long series of experiments and investigations that led finally to the method that Landerer uses at present were begun immediately after the discovery of the tubercle-bacillus by Koch in 1882. His first monograph on the treatment was published in 1892. For years the method was neglected, but of late years it has been commanding more attention because of the unusually good results it has yielded.

The considerations which formed the point of departure in his reasoning were the following: So long as the changes in the tissues caused by an infective agent

or its products do not progress beyond the stages of inflammatory hyperemia or serous exudation, complete restitution to the normal condition is possible. More severe processes which result in actual destruction of tissue, necrosis, are not capable of being followed by a return to normal, and here the most favorable conclusion is the formation of a scar.

The lesions of tuberculosis in the vast majority of cases with which we have to deal belong to the latter category, and the object of treatment is to convert tuberculous processes into solid scars. Now, Landerer says, it is well known that tuberculous areas have comparatively little tendency to become scarred up; in the vast majority of cases they show a tendency to be progressive, to form chronic abscesses, fistulous ulcerations, cavities, etc. He attributes this characteristic to the very moderate inflammatory reaction in and about tuberculous areas, and points for confirmation to the marked scarcity of bloodvessels in the tuberculous areas. There is too little blood present, and hence too little material for processes of repair, for the formation of scar.

This gives us the problem: To artificially provoke a more active inflammation about the areas. The treatment of lupus and slow-healing ulcers by caustics or ignipuncture is based on exactly the same principle.

Landerer now considered the fact that internal areas which are inaccessible from without can be reached by means of the blood-current, and further remembered that foreign particles injected into the blood are taken up by the white corpuscles and deposited by preference in regions where an inflammation or injury is present. He experimented on rabbits with an emulsion of balsam of Peru and found not only that after intravenous injections numerous white corpuscles carrying fine globules of the balsam closely surrounded the tuberculous foci in the lungs, but there was an evident beneficial influence on the course of the infection.

Without repeating the details of his years of careful experimental research, it will suffice to say that cinnamic acid was found to be the efficient constituent of the balsam of Peru, and at present the compound used for intravenous injection is the sodium salt of this acid, called hetol. It possesses all the efficacy of the original balsam and is free from its defects.

Landerer in his writings goes very fully into the consideration of the mode of action of hetol, and his theory of the same. In the following I give an outline of the observed facts as published by him, and corroborated by several other investigators.

In the first place he has determined by experiment upon animals as well as human beings that the injections are entirely harmless. There are no bad effects to the kidneys, and careful blood-counts show that there is no diminution of the red corpuscles, even excessive doses cause no discoverable injury to any organ.

The first effect to be noticed after the intravenous injection of hetol solution is an increase in the number of white corpuscles, chiefly confined to the multinuclear neutrophiles and the eosinophiles. This increase begins within an hour after the injection and reaches its maximum in from 3 to 8 hours, the number being doubled or more than doubled. After this a gradual decrease is observed until in from 24 to 48 hours the normal is reached. The capillaries about the diseased areas become dilated and crowded with leukocytes, which emigrate in numbers and begin to gather about the tuberculous foci, forming a dense wall. This on section can easily be seen with the naked eye.

In a few weeks new bloodvessels spring up and the granulations extend into the substance of the tubercular area, gradually absorbing and replacing the necrotic material of which it is composed. Finally this new granulation-tissue, as in normal healing, is converted into a scar. Small cavities are probably entirely obliterated, large ones are surrounded by dense connective tissue, with a smooth, dry lining of the same. The whole process may be summed up by saying that the treatment substitutes an active, aseptic inflammation for an inactive one, and the result is rapid cicatrization. The sensations of the patient undergoing this treatment are those of increased well-being commonly observed in persons improving under general hygienic and climatic treatment, except that the favorable signs appear more quickly.

Whether the increased activity in the healing process, which has been carefully followed step by step in rabbits, is due to the presence of the numerous leukocytes is as yet impossible to say. It is conceivable, as Landerer suggests, that hetol acts on tuberculous processes by forming innocuous compounds with the toxins of the tubercle-bacillus. This is a subject that cannot at present be cleared up.

There are several side-effects of the sodium-cinnamate treatment that are worthy of mention, partly because of the extremely interesting bearing on the question of the origin of uric acid in the blood.

In a recent address by Professor Ewald before the Medical Society of Berlin, in which he presented at length a report of his use of sodium cinnamate, he called attention to a marked drowsiness that he observed in many of the patients undergoing this treatment. Landerer stated that he had not observed this symptom and thought that perhaps Ewald's doses had been too large. I have noticed this symptom in quite a number of my patients, and can produce it at will by increasing the size of the dose. It does not appear until 10 or 12 hours after the injection, and usually with moderate dosage disappears in 24 to 30 hours. I think it indicates a dose that is rather too large, and it corresponds in the time of its occurrence with the period of diminution in the number of leukocytes in the blood and the probable destruction of many of them. The sensation is exactly the same as the so-called uric-acid fatigue, and according to Horbaczewski's theory of the formation of uric acid from the nucleins of broken-down leukocytes its pathogenesis would be comprehensible. A number of patients noticed and reported to me that they slept very soundly and long while they were taking the injections, more so than usual, and one found it harder to sleep each time the injections were stopped for a period.

In several patients there occurred repeated attacks of acute muscular rheumatism, which were absent during the long intervals of treatment, and seemed to have a relation with the injections, due perhaps to the same chain of causes as the drowsiness. In one patient with chronic gout the affected joints became painful two or three weeks after the treatment was begun on more than one occasion.

Generous doses, especially in severe and febrile cases, are apt to be followed within 24 hours by a slight rise in temperature. In my experience it has usually not exceeded a degree or a degree and a half, but by keeping accurate records of the daily temperature-curve it could be very plainly made out in several cases.

In my cases I have not noticed any decided tendency in the drug to cause hemorrhages. The moderate in-

inflammatory hyperemia observed in Landerer's experiments would lead one to expect small leakages of blood, but I have not observed these or larger bleedings, except in cases that had been having them before the treatment was begun.

While I am a firm believer in the great value of an out-of-door life, in rest and in the advantages, undoubtedly very considerable, of certain climates, especially the high and dry ones, in the treatment of patients with tuberculosis, still I recognize the fact that in many cases all these means are not enough and we want every possible help we can get in addition.

My experience with sodium cinamate in the treatment of consumption has given me favorable impressions of its effects. I think I have had evidence, good evidence, that it will quicken to a marked extent the healing processes when they are sluggish or altogether inactive, in some, though not in all, of the cases. Most of my experience in its use has been with rather severe cases, and the art of prognosis is here proverbially difficult, yet it seems to me that the results have been very encouraging, that is, better than they would have been without it, and I shall continue to use it, in addition to the other good methods that are available and that ought not to be neglected in any case.

STOMACH-CONDITIONS IN EARLY TUBERCULOSIS.*

By BOARDMAN REED, M.D.,
of Philadelphia, Pa.

In what has been incorrectly styled the pretuberculous, but should be called the incipient, stage of consumption, the most noticeable symptoms are often those of flatulent dyspepsia, with eructations and pyrosis or heartburn, with or without gastric pain, nausea, and even stubborn vomiting. These are sometimes symptoms merely of a lowered nerve-tone and at other times evidences of actual gastric involvement.

All the possible affections of the stomach may, of course, precede tuberculosis. Indeed, its development must be favored by gastric dilation, the various forms of chronic gastritis, and a failure or persistently depressed activity of the peptic glands, from whatever cause, nutrition being lowered in this way to a degree which may render infection possible.

Moreover, it is probable that, contrary to general belief, hypersthenic conditions in the stomach, such as hyperchlorhydria and acid gastric catarrh, are quite as compatible with tubercular infection as are the asthenic types of gastric disease. For it is now known that a large proportion of the cases of early phthisis—a preponderance of them, according to some observers—have an excessive secretion of hydrochloric acid.

Though not a very large number of reports of analyses of the stomach-contents in the early stages of tuberculosis are to be found in medical literature—and this question, therefore, cannot be said to have been positively decided—the evidence so far available points to the conclusion that, except in advanced cases with continuous fever, there is at least quite as likely to be an abundant secretion as a deficiency of HCl in the stomach.

Van Valzah and Nisbet,¹ in 47 cases of incipient phthisis, found in 10 no signs or symptoms of any

gastric derangement. Three out of the same series had chronic gastritis, with an absence of free HCl, a diminished proportion of combined HCl, etc. In 18 of the cases there were traces only of free HCl and diminution of secretion otherwise. In 13 of this last number there was mild, and in 5 severe, stagnation, with fermentation.

Among the 16 remaining of the 47 cases, 3 were found to have acid gastric catarrh—i. e., the sthenic form of chronic gastritis, with an augmented secretion of HCl; 7 had the same acid in excess, with motor insufficiency, stagnation, and delayed evacuation; and in the other 6 there was also hyperchlorhydria, with fermentation in all; while in 2 of them the stomach was unable to empty itself even during the night.

In 26 cases, first examined by the same authors during the stage of consolidation, 4 were normal as to gastric juice, 5 had chronic asthenic gastritis, one had a trace only of free HCl, and in 13 the secretion was variable, which means that sometimes it was in excess, and at other times normal or deficient.

Thus in 47 incipient cases there were 26, or 55%, with either a normal or overacid gastric juice; and of the 26 in the stage of consolidation, in 4, or 15%, the secretion was normal constantly, and in 50% more it was variable, that is normal or above a part of the time. In 65%, therefore, of the 73 comparatively early cases studied by Van Valzah and Nisbet the secretion of the peptic glands was normal or above at least a part of the time.

Riegel² quotes Klemperer as thus summing up the results of his observations in 14 cases, 10 of early and 4 of more advanced phthisis. In the beginning the secretory capacity of the stomach was mostly increased, often normal, seldom lowered; in the final stage markedly lessened. Klemperer found, however, that in all the forms of dyspepsia associated with tuberculosis, the motor function of the stomach was depressed.

Brieger,³ quoted by Riegel, studied 64 cases of tuberculosis, all except 6 of which were in a more or less advanced stage. In such a series there would naturally be a preponderance of depression in all the gastric functions. Still in 16% of even the more severe cases, Brieger found a normal condition of the gastric juice, while the same was observed in 33% of the cases classed as moderately severe. In the 4 incipient cases he found 2 with normal secretion and 2 with disturbed chemism, the inference being that in the latter there was a variable condition.

Riegel⁴ states that the results of his own observations accord in the main with those of Klemperer and Brieger.

Croner⁵ in 36 cases of early phthisis found in only 5 a complete failure of HCl. The total acidity varied from 21 to 80, but it was in most cases normal. He does not seem to have determined the proportion of free HCl, and must have relied upon imperfect tests of motility, since, contrary to most other observers, he reports not having found a lack of motor power in any of the cases.

Unfortunately for the cause of medical science and for the best interests of patients, physicians in general practice rarely make, themselves, or have made, analyses of the stomach-contents except when cancer is suspected, and the pulmonary specialists, I fear, have been in the past almost equally indifferent to the modern exact methods of studying the gastric functions. During 15 or more of my own busiest years of practice, when I

* Read before the American Climatological Association, in Washington, May 2, 1900.

saw many tuberculous cases, I have to confess having never made a chemical analysis of the gastric contents, nor even employed the simpler methods of determining the motor power of the stomach. And now that my work is limited almost exclusively to diseases of the digestive system, I do not often have the opportunity of seeing tuberculous patients. The following case, however, which is now under my care, presents some features of peculiar interest:

A married lady, aged 29, resident in a neighboring city, consulted me in November, 1899, on account of a stubborn and aggravated form of dyspepsia with light fever of a hectic type, slight perspiration at night, considerable emaciation and much debility. She had been treated for malaria with quinin, etc., and had also taken much creosote without apparent results, unless a very marked hyperchlorhydria could be considered a result. She has a lateral curvature of the spine dating from girlhood, and had worn for years at that time, a plaster jacket. The results of my examination in her case were as follows: Liver apparently about normal, kidneys not palpable. Heart normal as to size and sounds. Apex beat in right place, but not strong. Stomach enlarged from normal above to level of the umbilicus. Weak motility. Pelvic organs: Uterus slightly retroverted. Tender on palpation in region of left ovary, but no swelling could be made out in the adnexa.

Tuberculosis was naturally suspected, though no abnormal signs could be made out in the lungs. No cough, except after colds. No sputa could be obtained, and no bacilli were found in the stomach-contents. The blood was examined for the plasmodium of malaria twice, with negative results. Finally, diagnostic doses of tuberculin were cautiously administered 3 times at intervals of 12 to 24 hours, beginning with .11 cc. of a 1% dilution prepared with a .75% aqueous solution of carbolic acid and increasing to .5 cc. finally. After the third injection there was a decided reaction with a temperature 2 degrees higher than the average at the same time of day for a week or more before. There was also severe headache and backache, sleeplessness and some sharp pains about the neck and throat, but no other local reaction could be made out, except that a few slightly enlarged glands on both sides of the neck were markedly swollen and somewhat tender.

The secretory function of the stomach proved extraordinarily sensitive to drugs. It fell rapidly within a few days after putting her on full doses of soda and belladonna, all the free HCl disappearing, and then, on withholding these medicines, returned gradually to the normal. Even moderate doses of almost any tonic medicine showed a tendency to make the percentage of HCl go up again above 100. The treatment has been mainly by diet, outdoor air, and gentle exercises, with the help of galvanism to the spinal centers and over the course of the pneumogastrics in the neck, as well as of faradism through the stomach externally. Intra-gastric electricity was also administered for some time, but, though helpful, was not so well borne as it is by most other patients. At one time during the past winter, while she was in a suburb of Philadelphia under my care, there was, after some imprudence in diet, an increase of the gastric pain with such marked tenderness locally as to make one think of the possibility of gastric ulcer. She was then kept in bed either on the piazza or in a room with the windows all open for two weeks on a diet mainly of milk and given large doses of bismuth, according to Fleiner's method. The result was decided improvement in all ways. The patient has had periods of gaining markedly in strength and weight alternating with less well intervals, but there has been no fever since her recovery from the reaction following the diagnostic use of tuberculin 3 months ago. As to medicines this patient has tolerated well and responded favorably to 1-drop doses of creosote combined in capsule with codliver oil, minute doses of arsenic, and at times even when there has been too much HCl in the stomach, has found help from the administration of some of the digestive preparations made from the carica papaya plant. She has been at home for some time past, carrying out the line of treatment prescribed by me, though it is difficult to induce her to remain as much in the open air as is indispensable to a cure.⁶

The series of cases reported by Van Valzah and Nisbet, by Brieger and by Klemperer show that in early tuberculosis there is present very frequently—and probably in a majority of cases—a condition of the peptic glands which contraindicates the administration of any considerable doses, by the stomach at least, of highly stimulating remedies such as carbolic acid, creasote and its derivatives, the mineral acids, and most of the familiar stomachics. That is, in these cases when the gastric function is not entirely normal, there is usually either an excess of HCl, or a very impressionable and variable condition of the secretion—a condition in which the exhibition of stimulating drugs produces harmful irritation resulting often in hyperchlorhydria or acid gastric catarrh, which complicates the treatment of the tuberculosis and lessens the prospects of cure. Riegel's experience agrees with that of the authors cited, and my own case well illustrates the point just made, besides showing how tuberculosis for a long time may masquerade in the guise of a stomach trouble.

In the light of these facts, it is easy to understand why such directly opposite views are held by clinicians of equal ability as to the value of large doses of creasote and of other irritant drugs in tuberculosis. Whether the remedy does good or harm, depends mainly upon the condition of the stomach, and, it not having become yet the settled practice, as it ought to be, always to ascertain the state of the gastric functions before instituting active drug treatment in any chronic disease, a confusing contrariety of results follows such modes of treatment.

For exactly the same reason the profession is divided as to the value of codliver oil in pulmonary phthisis. Recent experiments prove that the oils markedly lessen the secretion of HCl in the stomach.⁷ In the cases therefore, in which the gastric functions are almost always depressed, as in the later stages of phthisis, codliver oil, or much fat of any kind, impairs digestion and injures the patient; whereas, in the cases of hyperchlorhydria, which are so often found in the earlier stages, the same remedy exerts a double influence for good, since here it tends to correct the injurious hypersecretion at the same time that it helps to fatten and strengthen the patient. In the cases between these extremes—cases in which there is a nearly normal gastric secretion—a moderate amount of oil may prove helpful for a time, and by means of an occasional analysis of the stomach-contents to see when it has begun to depress secretion unduly, advantage may safely be taken of its valuable medicinal and nutrient qualities.

Let me turn aside right here to advise that in doubtful cases, in which an analysis of the stomach-contents is not practicable, as well as in cases in which the gastric juice has been found to be about normal, it would be well to combine creasote or one of its congeners with codliver oil, so as to have the stimulating properties of the former neutralize the depressing influence of the latter upon the peptic glands.

It is generally conceded that the motor function of the stomach, which is always seriously lowered in advanced phthisis, is very apt to be depressed somewhat in even the earlier stages. That is, the muscular walls of the organ lose their tone and there results a tardy evacuation of the contents with consequent stagnation and fermentation. This weakened motility must be overcome before tuberculous patients can get well.

Drugs are of little avail for this condition, but breath-

ing exercises, especially in the open air, as from hill-climbing and bicycling and rowing, are highly curative in conjunction with a diet which is at once digestible, nourishing and not too bulky. We should avoid in such cases overloading the stomach, and much liquids should not be taken with the larger meals. Pulley exercises and gymnastics for the trunk-muscles generally are very useful. Massage of the abdomen can also do great good, except when the gastric glands are irritable and inclined to overaction; then it can overstimulate and do much harm, as has been pointed out by me in a previous paper.⁸ Intra-gastric faradism is also most helpful, but must be used with discretion.

The points emphasized in this paper may be thus summarized:

1. In early tuberculosis the secretion of HCl in the stomach is very frequently excessive, the peptic glands being in a condition of irritability which causes stimulant remedies of the creasote class to disagree and act injuriously.

2. Oils tend to depress the secretory function of the stomach and in consequence codliver oil is likely to help the cases which the creasote class of drugs hurt; but, on the other hand, hurts the cases in which the gastric secretion is inactive, the very ones in which creasote and the like often do good.

3. Therefore it ought to be the rule to ascertain the condition of the secretory function of the stomach before pushing either class of remedies.

4. When analysis of the gastric contents cannot be made, it is safer to combine creasote with codliver oil, so as to let one neutralize the other in their influence upon the stomach.

5. The motor function is very generally depressed in tuberculosis and must be restored before a cure can be brought about. Drugs avail little in this direction, but diet, exercise, especially in the open air, faradism and abdominal massage—except when hyperchlorhydria complicates—are all valuable means of effecting the result.

⁶ Since the above report was written the improvement of the patient has been marked. At the end of July she had gained in all 19 pounds, and had remained free from fever. Very slight impairment of resonance could then be detected at the left apex posteriorly, and there was a little roughness in the respiratory sounds there. She was eating well and almost free from dyspeptic symptoms as a rule. For a month she had spent most of her time in the open air and had been sleeping out at night.

THE FALLACY OF CLIMATE IN THE TREATMENT OF TUBERCULOSIS.

By J. W. KIME, M.D.,

of Fort Dodge, Iowa.

A MISTAKE that is far reaching in its consequences in the treatment of tuberculosis is the popular and, I regret to say, professional error that a specific climate exists and is of great importance in the therapy of this disease.

When we have examined a patient and find it necessary to inform him that he is suffering from tuberculosis the usual question is, "Where shall I go, Doctor? What climate do you recommend?"

The belief that a specific climate exists for this disease is as phantasmal as the vision of the fountain of immortal youth, and, even as the enthusiasts of this latter belief grew old and weary in their search for this fabled elysium, so do the seekers for health scatter their substance and exhaust their lives in the effort to find the land where basking in the sunshine and breathing in the air will magically remove the greatest scourge that afflicts our race. Nor is this the saddest feature of this error, for, even today, more than 90% of our profession are still pointing toward the West and South and are issuing the mandate, "Go;" while the pale wan army, trusting in the wisdom of its commanders, takes up its heavy burden and staggers forward to its almost certain fate.

Happily, Colorado and California have proclaimed that the Utopia sought does not there exist, that the land where climate alone brings health is to them unknown.

Sadly have they learned that not only do the strangers die, but dying leave behind an awful heritage that threatens the prosperity of their commonwealths. The native-born of every climatic resort are alike afflicted with this malady, but, seized with the fatal belief that somewhere exists the specific sought, they flee to die as others do, "among strangers and in a strange land." This talismanic superstition is as inseparable from this disease as are the cough, the hectic and the wasting frame. Yet it has been demonstrated over and over again that persons who have never resided elsewhere than in the climates most noted as antagonistic to tuberculosis have contracted the disease and have promptly died with it. This observation is a most common one in Colorado, California, New Mexico, Arizona, Florida, the Carolinas and in all the so-called climatic resorts.

This error concerning climate is the most cruel and the least excusable of the many that have been woven into the history of this malady. Consumptives in all possible stages, some dying before reaching their destinations, are advised by physicians who ought to know better, to go "to some other climate," and encouragement is given that health may await them there. Of all those sent, many more have been injured and their lives have been shortened, than have ever profited thereby.

There is so little in climate that it should be prescribed in but the rarest of cases, for in climatic resorts there is but little or no intelligent medical supervision, the patients depending wholly upon the climate, aided perhaps by a few stock prescriptions written by the family physician before leaving home. These same patients kept at home, with the comforts of the home life, under the careful supervision of an intelligent physician, would live longer and die more comfortably and more content than where, far from home and friends, their declining days are passed alone, homesick and heart-sick, among those whose only interest in them is a financial one. It is far more important that every act and every movement of the phthisical patient be directed by the physician than that a little rarefied air be breathed on some barren mountain peak. In far too many of these sad cases has the last dollar been raised at great sacrifice to themselves and to others when no possible good could come from the effort.

Writers on climatotherapy are so divergent in their views that we can accept few statements upon this subject as authoritative. It may be safely accepted, however, that that climate is of greatest value which permits of the greatest number of hours being passed in

the open air. With the exercise of proper care and proper intelligence there is no climate in this country that is not well adapted to the treatment of tuberculosis.

The ultimate solution of the tuberculosis problem lies in the direction of the special sanatoria that are being constructed all over the country and all over the world, and wholly independent of the question of climate. It is in these institutions that the best results are secured, both to the patients themselves and to the State at large. A much greater percentage of cases will be cured in these institutions than will ever be favorably influenced by the most noted of climatic resorts and these results will be obtained alike on the rugged New England coast, in the Adirondack mountain region, in the pineries of Wisconsin, in the elevated regions of the Carolinas, in the Valley of the Mississippi, in the Rocky Mountain region, in the rigid climate of Minnesota, and in the balmy sections of California, New Mexico and Florida. It is not a question of climate, of elevation, of heat or cold, of dryness or of moisture. Wherever an abundance of God's pure air and sunshine may be had, there may this disease be successfully treated. Results are the same in the high latitudes of Sweden, in the forests of Germany, in the mountains of Switzerland, in sunny France and Italy, and in the humid climate of the British Isles. In our own country like results are now obtained on the lower Hudson, on the coast of Massachusetts, in the Adirondack region and in the Carolinas.

The abundant sunshine of our arid Southwest may have certain advantages, but, unfortunately, relief there obtained is not of such a nature that it may be carried home to our northern and eastern portions.

Recently, much has been said concerning the acquisition of land by the various States in New Mexico for the purpose of founding State sanatoria in that arid climate. Such a movement would be ill-advised. Much greater good may be accomplished, with the same expenditure of money, by erecting these sanatoria in the various States supporting them. Such institutions, so placed, would be accessible to a greater number of people, would be nearer to their homes, and would be more liberally patronized. But a small percentage of consumptives could be sent from our Eastern and Northern States to sanatoria so inaccessibly located as in the region proposed, and while a few might be benefited by the climate, the great majority would be deprived of institutional care which is vastly more important.

On the whole, it is better that the question of climate be made subordinate to other considerations in the treatment of tuberculosis, and that our undivided efforts be turned in the direction of the proper treatment of these cases in the climates where they are found. By so doing we will cure more of our patients and save more persons from infection than if we attempt to transport a few isolated consumptives across the continent principally to enrich those who advertise "specific climates."

OPERATION IN TWO CASES OF TUBERCULOUS PERITONITIS.

By W. L. GRANT, M.D.,

of St. Thomas, N. D.

On March 28, 1900, Miss Julia N—, aged 20, came to me with the following history: For the past 2 months she had been increasing in size so that her clothes would not fasten about her. She had some wandering abdominal pain, and

an annoying cough, and a watery diarrhea. She did not feel like working and was gradually growing weaker. She had nursed her sister through an attack of pneumonia, my connection with the case having terminated but three weeks before, and the difference in appearance as to size was very noticeable for such a short space of time.

Upon examination I found a pulse-rate of 120 and temperature of 100°. Rales were to be heard over the lower part of the chest on both sides. The abdomen was prominent and all signs of fluid present. Operation was recommended and declined.

She was a faith-cure faddist and only came to me upon compulsion, her parents and friends suspecting her of being pregnant; she had been from home dressmaking in the city during the preceding winter. I also learned that 3 years previous she had been under treatment for pulmonary tuberculosis, and had had more or less trouble since that time. It was with much persuasion that she consented to treatment of any kind. I gave her 3 m. of creosote four times daily, and 4 grs. of calcium chlorid, with syrup hypophosphites co. three times a day, but with no signs of improvement, either in the lungs or abdominal cavity.

She rapidly grew weaker and lost flesh. The temperature varied between 100° and 102°, and the pulse was never below 120 and often 140 and more. During the first part of April she began vomiting and by the middle of the month very little food was being retained, and she was confined to her bed most of the time. The bowel movements, 3 to 6 at the beginning, increased to a dozen or more during the 24 hours. On the 24th she consented to operation, no food having been retained by the stomach for 4 days preceding.

On the morning of April 25, the peritoneal cavity was opened and about 4 gallons of clear fluid, much resembling urine in appearance, was removed. On enlarging the opening the whole peritoneum within reach could be felt studded with tubercles, these being particularly abundant in the region of the right ovary. The cavity was mopped out as well as possible and a gauze drain inserted. The fluid continued discharging for about a week, when the drainage was removed and the last stitch, a loose one, drawn tight. The temperature continued to rise to about 100° during this time. At the end of the first week there was a sudden rise of temperature with pain in the side, soon followed by all the signs of pneumonia in the base of the right lung. At the end of 36 hours the lung was completely pneumonic. It went through quite an ordinary course, except that there was no crisis. The lung gradually cleared up, but the temperature continued irregular for 3 weeks longer. The wound healed very nicely, except at the point of drainage, where there was a fistula leading down to the closed peritoneum. This was not finally healed until the beginning of August, since which time it has shown no signs of reopening.

There were no signs of fluid perceptible for two weeks after removing the drainage, when they again appeared, and a considerable quantity accumulated in the cavity. About the middle of May this reaccumulation reached its maximum, and then began to diminish until by the last of July there were no longer any signs of fluid. During this reaccumulation there was tenderness over the right ovary, where the tubercles had been found most abundant, but this disappeared with the signs of fluid.

The original pulmonary trouble began to improve almost immediately after operation. There were fewer rales and less cough until the pneumonia supervened. This was probably due almost entirely to the relief of pressure. But with the resolution following, all signs of trouble in the lungs gradually disappeared until there was neither a rale to be heard nor a cough. Rales, cough, and rise of temperature disappeared at about the same time—the beginning of June. The patient was kept in bed for 6 weeks from the time of operation, and was kept upon the same treatment outlined in the beginning. The creosote has been continued until the present time.

At the present writing, over 6 months after operation,

the girl is in fair health. She has gained in flesh and color, and has nursed her little niece through a very severe attack of ileocolitis. Altogether, she is in very fair condition, with a prospect of years of usefulness before her.

Another patient, John S., aged 36, a Swede, was operated upon on February 22, 1900. He had had slight pulmonary symptoms for some time and irregular painful conditions in the abdomen, particularly in the region of the appendix. There was but little fluid present, and that seropurulent. The appendix was rudimentary and not involved, so was allowed to remain. The next morning the temperature, which had been from 100° to 102.50° was normal and remained practically so thereafter. The drainage was left in 10 days, the same seropurulent fluid coming away during that time. The pulmonic signs remained for about 2 weeks, when they began to subside gradually. He remained in bed 5 weeks. Since that time he has gone about his work, harness making, and has had better health than for years. He was on creosote for 2 months, since which time he has had no treatment. He, too, was a firm believer in faith-cure and submitted to operation only as a last resort and after much entreaty by his friends.

In both cases the patients were opposed to operation on account of religious belief, and submitted to radical treatment only when everyone, themselves included, were persuaded that death was very near. I have no hesitation in saying that operation alone saved their lives at the time. But it has done more than that. In both cases a preceding pulmonary affection has been relieved, if not cured, though it is yet too early to make a claim of permanent cure.

When operation is so simple and practically free from danger, there is no reason why every case showing signs of tubercular peritonitis should not be submitted to operative treatment, unless there is so much involvement elsewhere that the case is hopeless on that account. And I should not feel that I had done my duty in a case where I had failed to make such a recommendation.

Had I such a case as that of Miss N——, first recorded, to deal with again I would close the abdominal cavity at once. This would avoid the danger of the fistula in the track of the drain and shorten the period of confinement to bed. Such cases as the second always demand drainage.

LUPUS VULGARIS OF FIFTEEN YEARS' STANDING SUCCESSFULLY TREATED AND CURED BY EX- POSURE TO X-RAY.¹

By A. EVERETT SMITH, B.S., M.D.,
of Olean, N. Y.

THAT lupus vulgaris is a skin disease of the most persistent and incurable type is evident to the student when he notices the long list of possible remedies which our best authors recommend. That the pathology and treatment of the disease has been little understood, most practitioners of any great experience must admit when they recall their fruitless attempts to alleviate these suffering patients. Such has been my experience. After using the remedies usually advised, I have seen the patient, uncured, drift on to others only to get similar results. To the conscientious physician such results are most humiliating, and ought to spur him on to diligently seek for other more successful treatment.

About two years ago, while making some experiments

with bacteriological cultures, I observed—the well-recognized fact, I believe—that cultures did not thrive so well when exposed to light. About this time, or later, I noticed some experiments were being made in Copenhagen, Denmark, applying this principle in the

The patient before treatment. The two patches were connected by a crust.

treatment of bacteriologic skin diseases. The light used, I believe, was the high-power arc electric light, the diseased surface being exposed to light-rays at stated intervals, with improvement in many cases. Among the cases so treated, lupus showed improvement.

I was desirous of making some experiments with cases of lupus vulgaris, believing that by the use of the x-ray much better results could be obtained than with the arc electric rays. I have accordingly the following case to report :

As he appeared about two months after the first treatment. All parts perfectly sound, and a healthy cicatrix formed.

Frank Nichols, aged about 80, of Shingle House, Pa., consulted me May 3, 1900, for an ulceration of nose and face which was involving his right eye. I found he had a lupus patch which extended from the left side of nose, going over the bridge and involving the right side of nose and inner

¹ Read before the Olean Medical and Surgical Club, August 1, 1900.

canthus of right eye and the inner thirds of the lids, together with the bulbar conjunctiva. He gave the following history: About 15 years ago he was slightly injured by a chip striking him on the nose, breaking the skin. It never healed over, but slowly increased in size, notwithstanding he had been treated by a score of physicians, a few skin-specialists and numerous quacks. About a year ago it invaded the eye, since which time it had progressed more rapidly in the mucous surface. There never was much pain; it bled occasionally and disfigured him much. His general health and family history were good. No specific taint was elicited.

I made a mask for the face of sheet lead, cutting a hole for the nose and diseased part of right eye, and with this on exposed him about every fifth day for 20 minutes at a time, the diseased surface being placed about 2 inches from the light. He received in all 12 treatments. No medicine whatsoever was allowed. He was using applications of vaseline at first, but that was denied him. Marked improvement commenced after the second treatment, and was not interrupted until the sore was completely and entirely healed. After the second treatment healthy granulations appeared and healing was remarkably speedy. There was no burning from the light, or any other unpleasant symptoms complained of, except a slight headache and a decided "crawling sensation" in the sore after the first two treatments. The cicatrix has produced a slight ectropion by everting the inner end of the lower lid, and has drawn the upper lid down and in, but vision is normal.

I do not claim priority in the use of x-ray in this treatment, though I have not noticed reports of its having been used previously for this purpose.²

THE DISEASES OF THE BRONCHIAL GLANDS.*

By J. N. HALL, M.D.,
of Denver, Colo.

AMERICAN medical literature is singularly barren upon the subject of the diseases of the bronchial glands. Vastly more attention has been bestowed upon scores of subjects of so little comparative importance that the oversight is almost inexplicable. It is with the hope of calling attention to this little-studied field, so far as our textbooks deal with it, that I address you.

From the great number of cases of diseases of these glands quoted by English writers I feel certain that they are much oftener and more seriously involved in English children than in those of this country. Osler, who has doubtless had as wide a clinical experience as any American physician, formerly stated, although I cannot now find the reference, that he had never seen bronchial obstruction from pressure of enlarged glands, and but few cases have been reported in this country in comparison with these abroad.

The bronchial glands, over a score in number, are grouped about the bifurcation of the trachea, being larger and more numerous upon the right than upon the left. Some of the largest are found immediately under the arch formed by the two main bronchi. A chain of small glands extends upward along the left recurrent laryngeal nerve as it winds under the aorta, and another along the right as it passes under the subclavian artery. These glands intercommunicate freely, and receive also the lymphatics of the neck, chest and the organs therein contained, especially the trachea, the bronchi, the lungs and the pleurae. Their relationship with the supraclavicular glands is affected, according to Baréty, by the

group of glands found behind the sternoclavicular articulation, made up by the confluence of the chain situated in front of the cervical fascia, the internal mammary glands, and the tracheobronchial chain; with this group the supraclavicular glands communicate freely.

Along the branches of the bronchi extending into the lungs are smaller lymphatic glands, of less interest pathologically, but nevertheless capable of causing trouble similar to that originated by the tracheobronchial glands on a larger scale. They are found near the primary divisions of the bronchi, especially posteriorly, we are told by Quain, and at the bifurcations of the branches of the pulmonary artery.

All of these glands are relatively larger in the child than in the adult, and, because of the activity of the lymphatic system in the child, they are especially prone to be involved by disease.

These glands have a free vascular supply from the bronchial arteries, and receive the afferent lymphatics from the lungs, pleurae and neighboring parts. Guéneau de Mussy and Peter¹ have shown that lesions of the nasopharynx and even facial erysipelas may react upon the bronchial glands through the intervention of the deep cervical glands.

As the bifurcation of the trachea is found opposite the fifth dorsal vertebra posteriorly, and behind the lower end of the manubrium sterni anteriorly, and as the bronchial glands lie chiefly at or above the bifurcation, it is at or above these points that we look for the chief signs of their presence when enlarged.

The glands are enlarged in conjunction with the involvement of the lymph-glands of the entire body in leukemia, pseudoleukemia, leprosy, syphilis, general tuberculosis and possibly of other diseases. Primary lymphosarcoma and lymphadenoma, the latter formerly mistaken for cancer, also occur, as well as cancer and fibroma. The largest glands are found in connection with disease of bone, especially tuberculous disease.

Simple lymphadenitis arises from any acute or chronic process inflaming the organs the lymphatics of which reach the bronchial glands. As examples of these diseases we may mention acute bronchitis, pneumonia, bronchopneumonia, pleurisy, chronic bronchitis, the subacute or chronic lung-changes following measles and whooping-cough—typhoid fever and diphtheria.

Marfan¹ states that the individual ganglia may reach a diameter of 2 or 3 centimeters. During the acute stage of the inflammation they are reddish or liver-colored, becoming, as the process becomes subacute or chronic, paler, firmer, and even sclerotic.

At the postmortem we find, aside from the above changes of simple lymphadenitis, many other conditions of interest. In this region, where, from the extensive mining interests, great numbers of men are affected with miner's phthisis, the absolutely black glands described by Wilson Fox² are frequently seen, a real melanoma, often softened into a black, pulpy mass. The gritty feel, from the presence of particles of coal, silica or other mineral substance, is notable, these particles being arrested by the glands as by so many filters, until the limit of capacity is reached. Dust particles not arrested by the mucous corpuscles, swept thence outward by the ciliated epithelial cells, and expectorated, are taken up by the swollen alveolar cells, if not too numerous. If so, they penetrate the mucous membrane, reach the lymph spaces, and even enter the lymph current to be carried to the small lymph nodules surrounding the bronchi and the bloodvessels; to the in-

² I wish to acknowledge the kind assistance of my friend and colleague, Dr. Joseph C. Clark, of Olean, N. Y., who so cordially placed his static x-ray machine at my service in this case.

* Presidential Address before the Colorado State Medical Society, June 21, 1900.

terlobular septa beneath the pleura, or along the lymph channels to the bronchial glands, in the cells of which they lodge. (Arnold.) Weigert²⁶ has shown that when densely pigmented glands adhere to the pulmonary veins, some of the carbon particles may pass into the general circulation, to be arrested in the liver and spleen, although in all but extreme cases the bronchial glands are a sufficient defense to the system.

The particles deposited in the follicular cords of the tracheal and bronchial glands and the smaller lymph nodules finally excite proliferation of the connective tissue elements (Osler), the glands becoming sclerotic, as above described. M. Carrien¹ lays stress upon the impermeability of the hypertrophied glands as a condition precedent to pulmonic anthracosis. Marfan¹ ascribes the development of emphysema in pneumoconiosis to the damage to the lymph channels and consequently to the alveolar epithelial cells, atrophy of the alveolar walls resulting.

It is, however, in tuberculosis that we find the most important changes in the bronchial glands. They are greatly enlarged and often show tuberculous granulations, although we may find, as Fox has mentioned, a true "lymphadenitis tuberculosa, in which, from the swelling and diffuse infiltration, no granulations may be discernible." Cheesy degeneration is often found, but it is not a necessary part of the transformation, for the swollen gland and probably the tuberculous granulations may have fibroid metamorphosis, thickening of the reticulum and septa, and the whole tract of glands becomes a glistening, semicartilaginous substance with scattered nuclei through it. The glands are likely to be deeply pigmented, especially those nearest the lung, are hard and resistant upon section, and, by a continuation of the process outlined, may shrink to less than the normal size. They adhere, not only to each other, but to the connective tissue of the mediastinum, and the edges of the lung. In other cases we have all gradations "from the grayish granulations sown in a congested parenchyma to the uniformly yellowish and caseous gland, sometimes with a thick, fibrous capsule, sometimes a real cyst of pus, sometimes more dry and cheesy;" while a true cure results in those cases where lime salts have been deposited in abundance. The tuberculous bronchial glands may be found deep in the lung. Cruveilhier states that the glands at the bifurcation of the trachea enlarge most in tuberculosis, although the others may attain a very large size.

In a recent case at the Arapahoe County Hospital, in which the characteristic cough and other signs existed during life, so that I had entered the diagnosis as "pulmonary tuberculosis with enlarged bronchial glands," a single gland near the bifurcation of the trachea was an inch in diameter, and entirely caseous. Many others were found enlarged, but less matted together than one would have expected. Extensive and advanced tuberculous lesions were found in both lungs. We should note, however, that Ziegler lays especial stress on the frequent presence of such large glands in cases with but a small focus of disease in the lung. E. Smith states that if the glands remain large in any case they are presumably tuberculous.

It has long been recognized that the bacillus of tuberculosis is found in the bronchial glands of children and adults, and may be demonstrated by inoculation experiments, if not microscopically. Thus H. P. Loomis³ found that the bronchial glands were infective to rabbits in 8 out of 30 cases in which no signs of tuberculosis

were found. Pizzini⁴ injected, with aseptic precautions and control animals, the bronchial glands of 40 patients dying suddenly, all adults but one, and not appearing tuberculous, into animals, and, throwing out 10 in which mixed infection occurred, found that 42% of these animals developed tuberculosis. Of those injected with the cervical glands from the same subjects, but 2% became tuberculous, and none of those upon whom the mesenteric glands were used.

In children the bronchial glands are tuberculous in most cases coming to autopsy. Northup's record of 125 autopsies in which these glands in every one were tuberculous has often been quoted. In fact, this is by no means a new discovery, for Steiner,⁵ in 1865, found the bronchial glands macroscopically tuberculous in 275 of 302 children. Spengler⁶ concludes that the bronchial glands are the most frequent seat of primary tuberculosis, and the tendency amongst pathologists is to agree with him. Thus Weigert,⁷ states that infantile tuberculosis is not primary in the lungs as commonly as in the adult, but secondary from the bronchial and pulmonary glands. He quotes many authorities who agree with this view.

The influence of these glands in the origination of other tuberculous processes than those of the respiratory tract has been underestimated in the past. Bertalot⁸ found tuberculous bronchial glands in 20 out of 24 children dead of tuberculous meningitis, while but one showed primary tuberculosis in the mesenteric glands. Reimer,⁹ in 42 cases of the meningeal infection, found caseous bronchial glands 36 times, miliary tuberculosis of these glands 5 times, but one being free from involvement.

Henock¹⁰ reported 17 cases of tuberculosis of these glands in 18 of meningitis, in 3 the mesenteric glands being affected.

Further quotations would be superfluous. The wonder is that, with the almost constant involvement of these glands, tuberculous meningitis is so comparatively rare.

Lesage and Pascal¹¹ explain the origin of tuberculous meningitis through communication of the lymph vessels of the neck with the perivascular lymph spaces of the brain-membranes. The cervical glands are infected intermediately. It is probable, they state, that infection may occur by way of the spinal canal.

Weigert¹² believes that the disease remains local in the bronchial glands owing to closure of the lymph vessels leading from them. A lack of tendency to soften is favorable, for tuberculosis is often spread by the breaking down of the glands which results from a mixed infection.

Induration of the glands from the presence of mineral dust, with the development of fibroid contraction, and consequent smaller blood-supply and lack of oxygen, is to be considered a conservative process as regards tuberculosis elsewhere.

General miliary tuberculosis probably originates more frequently from the bronchial glands than from any other source. Communication of a disintegrating gland with the blood-current by ulceration into a vein is probably certain to cause a general infection.

Guthrie¹³ believes that the thoracic glands are the place of origin of many cases of tuberculous meningitis, and that these glands may become tuberculous not only through inhalation of bacilli, but by the entrance of the latter through the lymphatics of the pharynx, tonsils, and esophagus, intestines, and abdominal glands, and even from the thoracic duct by way of the pulmonary

circulation. We should particularly insist upon the predominating influence of the tracheobronchial glands as compared with any other lymph-glands, in the origination of tuberculous processes elsewhere in the body.

The lung may be involved by way of the lymphatics, a lymphangitis, connecting the distant focus in the lung with the glands, setting up the process.

As evidence that the lymph-glands in the child are often primary sources of pulmonary tuberculosis we have the statement by Welcker that the disease often involves both lungs, and spreads outward from the hilus, contrary to the usual rule in the adult.¹⁴ I believe it is quite probable in some cases in adults in which we recognize tuberculosis in the apex of the lower lobe of the lung after that at the true apex, that it comes from a local infection from caseous, ulcerating glands.

Practically all phthisical patients have tuberculous bronchial glands, while the bronchial phthisis of the older writers, a tuberculosis of the glandular apparatus rather than the lung, is much more frequent in children than in adults. It has been suggested that they inhale the bacilli during babyhood from unusual exposure in crawling upon the floor, but extreme susceptibility seems to me to be the most important factor in the infection of these glands in childhood, for all residents in civilized communities inhale the omnipresent micro-organism.

Parrot formulated the statement that tuberculosis of a group of glands always followed tuberculosis of the tributary viscera. This so-called law is now known to be incorrect, for the bacillus may penetrate the bronchial mucous membrane or other membranes, and reach the lymph-glands without affecting the lung or other organ at the point of entrance. Thus we have undoubtedly in the past failed to realize the vast importance of the bronchial glands in filtering out from the lymph stream the individual bacilli, and holding them prisoners in a place of comparative security. The organism is for a long time protected. It is only when enormous numbers of bacilli invade the respiratory tract that the glands are overpowered. Then, in the performance of their function, they sacrifice their own integrity, offering themselves as a forlorn hope in the attempt to prevent the general infection which is imminent.

Manfredi¹⁶ shows that the lymph ganglia not only hold but tend to render innocuous the tubercle-bacillus, and many other microorganisms as well. Schleich⁶⁶ presents the most convincing evidence of the great value of this process. Marfan and Manu⁵⁹ have found in the glands, even of the newborn, Friedländer's bacillus, Frankel's pneumococcus, and the streptococcus. None of these infections, however, compare in frequency or importance with that by *Bacillus tuberculosis*. Other bacilli of less serious import are also found, notably the staphylococcus.

The enlarged glands frequently undergo the caseous metamorphosis, and remain innocuous. Calcareous matter may be expectorated as a result of the disintegration of such a gland, or a true lung stone be expectorated.

Charles West found but 6 out of 72 cases of enlarged bronchial glands in children in which the cretaceous deposit had occurred, but the proportion is greater in adults.

Hoffman¹⁶ states that in favorable cases the sloughing gland may be coughed up, but neither he nor any other author, to my knowledge, has quoted a specific instance

of such an occurrence until the publication of my own probable case.¹⁷ I have there given references to 15 cases, in 14 proven by autopsy,¹⁸ "in which obstruction occurred in the air-passages from a sloughing bronchial gland too large to be expectorated." "In the remaining case, some partially disintegrated fragments of the gland were removed by means of a catheter through the tracheotomy wound, when it was found that the operation had afforded no relief, and a still larger piece was ejected afterward. The child recovered." (Peterson's case.)

After noting the scant mention of the diseases of the bronchial glands in the textbooks, and the slight attention given to them in works upon physical examination, it is a great surprise to find how the literature teems with postmortem records of the finding of the glands in the air-passages, or the cavities, especially near the root of the lung, left by their disintegration. Poland,¹⁹ Parker,²⁰ Nachod,²¹ Bayeux and Audion,²² Poupon,²³ Eichhorst,²⁴ Ogle,²⁵ Voelcker,²⁶ and a score of others have noted many such cases. So frequently have they been found that one should always bear in mind the accidents from the diseases of these glands in the consideration of possible causes of sudden death, especially in children. Thus Parker²⁶ reports a case of sudden dyspnea, resulting fatally in a previously healthy child, from rupture of a gland into the trachea just above its bifurcation, and Gulliver, Goodheart, and others have seen similar ones. The reported cases of sudden death from similarly diseased glands in children previously ill are too numerous to mention.

As we shall see, the acute process, either of simple or tuberculous origin, not infrequently ends in suppuration. The gland, as the inflammation proceeds, adheres to the bronchus, the trachea, the esophagus, the pericardium, the pleura, the pulmonary veins, the pulmonary artery, or even the aorta, and finally ulcerates through the intervening wall. We then find, as secondary processes, pericarditis, pleurisy, pneumothorax, infection of adjacent lung, hemorrhage, establishment of a cavity, caused either by the sloughing out of the glandular mass or necrosis of adjoining infected lung, or both, pulmonary abscess, or pulmonary gangrene. The cavities from sloughing glands, according to Rilliet and Barthez,³⁶ have no bands crossing them, as do those in lung parenchyma, for in the latter case the resistant vessels remain until the last. The interior wall is smoother also. In such a cavity Cruveilhier even found a lumbricoid worm, after perforation of the esophagus.

Pericarditis and pleurisy may occur from contiguity, without perforation. The pericarditis may be typically tuberculous, a large, caseous mass, or a thin membrane with sparsely scattered tubercles.³⁷ (Baréty.)

The hemorrhage may be immediately fatal, as in case the pulmonary artery or the aorta be opened, or less severe in case the smaller branches be affected. Many hemoptyses are of this latter origin, being often sharp and repeated in character. If the rupture occur into the esophagus, much pus may be immediately evacuated with recovery, as in the Denver case reported by Dr. H. B. Whitney,³⁸ or the Chicago one by Dr. F. E. Waxham.³⁹

If the bronchial tract or the pulmonary parenchyma is invaded, an intense capillary bronchitis is often set up, resulting, in many cases, in abscess or gangrene, as indicated above. It has been suggested that these processes may arise from compression of the vagi, repre-

senting the termination of a *vagus* pneumonia, although many of them are from direct pulmonary damage.

The secondary enlargement of the bronchial glands from malignant intrathoracic disease we need mention but briefly, since the original disease rules in diagnosis, prognosis and treatment. Powell²⁹ has seen the left bronchus narrowed by compression in carcinoma of the glands, the head of the pancreas being involved probably primarily. Bennett has seen abscess of the lung, with similar obstruction of the left bronchus, from cancer. It is noteworthy that the glands are not always involved in cancer of the lung, and may remain free in cancer of the esophagus even where perforation of the bronchus or of the trachea had occurred.³⁰ Tumors of the mediastinum are said by Hoffman¹⁶ to cause enlargement of these glands but rarely, contrary to our expectations.

Since the involvement of the bronchial glands in lymphoma and lymphadenoma is but a minor part of a general disease, we shall not study these conditions at length, for it would lead us beyond the boundaries of our subject.

In gangrene of the lung, Schroeder³¹ saw the bronchial glands gangrenous, and the lymphatics leading to them filled with gangrenous matter. Cruveilhier³² and Lebert³³ have reported cases in which gangrene of the bronchial glands apparently preceded that of the lungs.

The especial interest of the glands in question lies as much in their situation as in their importance in the economy. J. L. Smith,³⁴ for instance, states that the bronchial and mesenteric glands are the only ones in the body which materially increase the danger of tuberculosis, or give rise to special symptoms, these symptoms being mechanical, or due to rupture. Meigs and Pepper³⁵ call attention to the fact that the bronchial glands cause trouble from the immovable organs and unyielding walls about them, while the mesenteric glands, situated amongst freely movable organs in a cavity which easily accommodates its walls to its contents, are comparatively innocuous.

Aside from the infections of other organs, chiefly occurring in tuberculosis of the bronchial glands, these ganglia, as Rilliet and Barthez long ago pointed out, cause most damage by compressing neighboring organs, or by adhesion to them with consecutive perforation. The arteries, being movable and resistant, often escape harm. The aorta may be pushed upwards. Baréty believes that even a simple lymphadenitis predisposes to tuberculosis of the lung by compressing the pulmonary artery and thus lessening the blood-supply. It is well known that phthisis is frequent in narrowing of the pulmonary artery from any cause. A suggestive fact is found in the greater liability of the branch to the upper lobe to pressure from this source, for here pulmonary tuberculosis ordinarily begins.

The enlargement of the bronchial glands, from whatever cause, leads to pressure upon contiguous organs, and we shall profit by a review of the mechanical disturbances so produced.

The upper mediastinal space, in which the glands lie, may be divided into the anterior, or vascular plane, and the posterior or tracheoesophageal plane. The former contains the vena cava superior and brachiocephalic veins, the aorta and its branches, the pulmonary arterial system, and the pulmonary veins; the latter, the trachea, bronchi, esophagus, the pneumogastric and recurrent laryngeal nerves, and branches of the sympathetic system.

The symptoms of compression relate to the organs affected, and therefore those tumors, glandular or otherwise, in the anterior plane, as Rendu¹ has pointed out, are generally of slow evolution, venous pressure being the most prominent symptom. Bulging of the sternum and contiguous chest-wall, and corresponding dulness, are to be found frequently. The disease in this region is more likely to be malignant, frequently affecting the thymus gland, while the posterior plane is more often involved by lymphatic growths.

In this posterior plane, then, and usually from glandular enlargement, we are likely to find evidences of mechanical interference with respiration, from compression of the trachea or bronchi, hoarseness or aphonia from pressure upon the recurrent laryngeal nerves, dilated pupil from irritation of the sympathetic, or contracted pupil from its paralysis; dysphagia from compression of the esophagus or of the filaments of pneumogastric origin supplying its upper portion; vomiting of similar origin, or tachycardia, either constant or intermittent, from abolition of *vagus* influence from pressure.

Compression of the phrenic nerve gives rise to diaphragmatic neuralgia, to hiccup, and to a definite phrenic dyspnea, we are told by Marfan. It should be remarked here that certain of these, as of following symptoms, are rare, and have not come under my personal observation, unilateral salivation has been noted from sympathetic paralysis. The weakened pulse of inspiration, reminding one of the *pulsus paradoxus*, in which, however, the pulse is slowed but not weakened, is accounted for by pressure upon the great vessels. It is at times unilateral, at times found in both arms. A systolic murmur may originate from pressure upon the base of the pulmonic artery, or the aorta.

Tachamer¹⁶ has seen the fingers clubbed, a result of interference with the venous return, as in other chronic chest diseases. Hoffman lays much stress upon venous stasis as the result of pressure, showing itself in the whole upper portion of the system. If the vena cava superior be involved, the stasis occurs in the facial veins, and over the shoulders and arms, sometimes unilaterally. The anterior surface of the thorax becomes covered by a network of veins, if the compression be complete, and the blood enters the vena cava inferior by anastomosis of the greater and lesser azygos veins, and the intercostal, internal mammary, epigastric, abdominal, subcutaneous and circumflex iliac veins. (Marfan.) If the collateral circulation fails, edema of the hand and face occurs, with cyanotic lips, injected eyes, epistaxis, vertigo, headache, and, if we are to credit Rilliet and Barthez,³⁶ meningeal hemorrhage.

If the pulmonary veins are compressed, edema of the lungs, hydrothorax, and occasionally hemoptysis may be found. Hydrothorax may be unilateral, Marfan states, that limited to the right being found where the vena azygos major alone is compressed.

Ruhle³⁷ believes that dilation of the left ventricle may occur from pressure of enlarged glands upon the aorta.

Cruveilhier (quoted by Fox²) states that suffocation in infants probably occurs occasionally from pressure upon the laryngeal and *vagus* nerves. If thick mucus closed a glottis already in a state of spasm in a weak child this would be readily explicable.

Since venous obstruction, the most prominent symptom of tumor in the anterior mediastinum, is borne with much less difficulty than the symptoms noted above as found in the glandular enlargements of the posterior plane, the latter are more immediately dangerous, suffocative acci-

dents being especially to be feared. Although, with any considerable increase in the size of these glands many organs are pressed upon, the brunt of the trouble is usually felt by certain structures more than by others. By inflammation the glands become adherent to contiguous organs, and may, indeed, show the most varying symptoms of pressure, as the different structures are more or less involved.

Of the utmost importance is the pressure exerted upon the trachea and the larger bronchi. From the position of the larger glands these tubes rarely escape, the right main bronchus being most frequently involved.

With increasing pressure the entrance of air is more and more interfered with. If the lower end of the trachea be affected, the respiratory murmur upon both sides of the chest is enfeebled, while but one side, most often the right, is so affected if a main bronchus is compressed. The French have described particularly³⁸ the tracheobronchial *cornage*, caused by the passage of the inspired air through the narrowed tube, a sign of the first importance, and most noticeable in my own recent case of obstruction. With this is commonly associated *tirage*, or inspiratory retraction of the thorax, as a whole if the trachea is obstructed, otherwise limited to the side of the affected bronchus; due, of course, to the difficulty of filling the air vesicles because of the obstruction.

If we add to these two signs the enfeebled vesicular murmur with conservation of the vesicular resonance, bilateral in case of tracheal obstruction, otherwise unilateral, we have sufficient evidence upon which to base a diagnosis of respiratory obstruction. If the signs be bilateral, we must exclude edema of the glottis, spasm of the glottis, polyp and membranous exudate, for tracheotomy has been uselessly done for compression of the trachea by simple lymphadenitis, as for aneurysm. In all of the last-mentioned diseases, however, the voice is affected, while the larynx remains immobile and the voice comparatively clear despite the most violent dyspnea, if the obstruction be below it—the latter sign being strikingly prominent in a case I have recently seen with Dr. Love, of Denver.

From the compression of the air-passages the number of respirations is decreased, inspiration and more especially expiration being prolonged, we are told by Grancher.⁶⁸

Marcy long ago observed the increased frequency of the pulse in such respiratory difficulty, contrasting markedly with the slow respiration. Slowing of the pulse from pneumogastric irritation must not be forgotten. The expansion of the affected side is notably diminished, so that finally a unilateral thoracic retraction may be noted, as after pleurisy. Guéneau de Mussy³⁹ even believes that the scoliosis with retracted chest and lowered shoulder in children is commonly from this cause.

Lagging of the affected lung is noticeable.⁴⁰ The indrawing of the affected side is greatest below because of the fact that the air reaches this part of the chest last, while the diaphragm pulls in the attached ribs in its contractions.

Long-continued obstruction frequently produces a shortened anteroposterior diameter of the chest. Often-times the patient lies upon the side of the enlarged glands, as upon the side of a pleural effusion, obviously that he may use the better lung. Quain mentions a boy, who recovered, whose favorite position was on his face and knees.

Patients with obstruction of the trachea or a main

bronchus eventually perish by (1) slow suffocation, (2) pulmonary edema, (3) bronchopneumonia, (4) pneumonia, (5) gangrene, (6) abscess of lung, or (7) by immediate suffocation from collapse of the weakened cartilages of the tube at the point of compression. To these causes we should obviously add (8) sudden suffocation from lodgment of a sloughing gland in the air-passages, and (9) obstruction of a much narrowed canal by tough mucus.

We should here speak of the sudden exacerbation of symptoms, relating either to air-passages or to other structures, from sudden fluxion to the periganglionic tissues and consequent increase of pressure. Such fluxion, coming from exposure to cold or other irritation of the respiratory tract, may cause very serious symptoms in a few hours, in the more advanced cases, especially if obstruction from thick mucous secretion be superadded.

From the position of the esophagus we may readily see that dysphagia must result in some of the cases we are studying. I have seen it in at least two cases. Spasm of the tube is also found at times, as mentioned by Hoffmann. The obstruction may not be apparent upon passing the sound, and is thus at times thought to be hysterical. Hoffman believes that it may be due to pressure on the branches of the vagus supplying the esophagus as well as to direct pressure upon the tube. It may diminish or disappear upon the bursting of an abscess of the glands. Marfan¹ mentions that direct pressure gives rise to constant difficulty of swallowing, while painful esophagismus and pharyngismus arise from pressure upon the nerve-fibers above-mentioned supplying the upper esophagus and the pharynx, as in the case of other mediastinal tumors. It is stated by Quain⁴¹ that dysphagia was present in 10 of 58 cases, in one case especially for liquids.

The laryngeal and tracheal symptoms caused by pressure from the diseased glands are of the greatest interest. Marfan states that at times the larynx does not move upon swallowing and during respiration, because of fixation of the trachea in the mass of glands, evidently.

The trachea may be pushed forward or displaced laterally, but the signs pertain to cases of mediastinal tumor of other than glandular nature as a rule.

The paroxysmal cough, so strikingly like whooping-cough, is the most prominent symptom in many cases. It is stated by Hoffman¹⁶ that the pressure of the glands near the tracheal bifurcation causes the specially severe cough seen in certain cases, because of the presence of the recurrent laryngeal nerves in this situation, where they are subjected to pressure, to traction or to hyperemia from contiguity to the inflamed glands. The expectoration is often mucous, as in bronchial catarrh, and may contain pus if glands be breaking down, often mixed with air. Calcareous particles from the disintegrating glands may be expectorated. Many patients raise absolutely nothing. (Quain.) The cough differs from that of pertussis in its noncontagious character, in the fact that there is no inspiratory whoop, and in the longer duration, not subsiding in a few weeks as in the contagious disease. Notable cough was present in 39 out of 58 cases, in 21 of them being the most troublesome symptom. (Quain.)

Hoarseness or aphonia may result from involvement of the recurrent nerves, especially of the left, which passes deeper into the mediastinum than the right, and is therefore more subject to pressure.

Eustace Smith⁴² states that many supposed cases of

asthma in children are paroxysmal attacks of dyspnea from the irritation of enlarged bronchial glands. Day⁴² believed that laryngismus stridulus was due to the same cause. He also mentions that the spasmodic cough, lividity and threatened asphyxia may simulate asthma closely, and may end fatally.

Much interesting work has been done in studying the effect of compression of the recurrent laryngeal and other nerves upon the larynx. Paralysis of all the muscles of the glottis leaves it open as in the cadaver. (Krishaber.⁴³) Paralysis of one cord cannot produce dyspnea. The only paralysis producing closure of the glottis is that of the abductors, the cricoarytenoidei postici, allowing the opponents to act unopposed. But double paralysis of this nature is rare, and none of the cases quoted by Ziemssen or Riegel were caused by tumors. Johnson reports one such case. (Quoted by Fox.³)

Further, the recurrent nerves supply nearly all the muscles of the larynx, and paralysis of any single muscle or pair of muscles could hardly occur from compression of the whole nerve. Stimulation of the recurrent may give dyspnea, but does not always do so, while aphonia is the most constant symptom of paralysis.

Krishaber states that dyspnea, in these cases, if the voice be preserved, demands tracheotomy (or in these days, intubation,) since the preservation of the voice indicates that the trouble is spasmodic, the nerves therefore being still intact. Dyspnea with loss of voice is not benefited by the measures indicated, for such dyspnea, not being due to paralysis alone, must be due to pressure upon the trachea below, not capable of relief by these measures; hence they are useless. As paralysis may coexist with spasm, however, these indications are less valuable than they otherwise would be. The most urgent dyspnea may arise in paralysis of the larynx from sudden stopping of the glottis by accumulated mucus. Compression of the trachea probably explains most cases of severe dyspnea from enlarged bronchial glands, either by intermitting degrees of pressure, or by superadded accumulation of mucus.

Fox states that paroxysmal dyspnea without compression of the trachea or aphonia has been proved postmortem to be due to a thrombosis of the pulmonary artery, although simulating the former condition.

Of Quain's 58 cases, 13 had dyspnea, in 4 of these cases resembling spasmodic asthma, and occurring especially at night.

Quain found pain at the fourth or fifth dorsal vertebra on one side or on both in 22 out of 58 cases. It occasionally existed under the manubrium. Tenderness may coexist with pain in either locality.

We have seen that vomiting occurs from irritation of the pneumogastric nerve in certain cases. It is probable that this symptom in phthisis occasionally arises in like manner, from the pressure of tuberculous glands.

The theory of de Mussy,³⁹ that whooping cough is simply a manifestation of pressure by enlarged bronchial glands, has not been established. He went so far as to suggest that this disease was an exanthem of the bronchial mucous membrane causing great enlargement of the glands, which pressed upon the recurrent nerves and thus gave rise to the crouping cough and vomiting. Neither has the theory that spasmodic croup depends upon pressure from the diseased glands obtained credence.

J. L. Smith³⁴ states that enlarged bronchial glands may so interfere with the return circulation from the

brain as to cause the child to present most of the symptoms of tuberculous meningitis, serum being probably effused into the cerebral cavities. In one of his cases he states, however, there was no sighing respiration nor vomiting, nor was the temperature that of meningitis, so he was not deceived.

The extreme wasting spoken of in Hare's monograph as due to pressure of mediastinal tumor upon the thoracic duct I have not found mentioned in the literature of the bronchial glands.⁴⁵

Barry⁴⁴ saw a fatal result in a woman of 71 years, emphysematous, but not tuberculous, from hemorrhage from the vena cava superior, into which a gland had ulcerated. Thus neither age nor absence of the macroscopical signs of tubercle give any assurance of freedom from this form of death. In Griffin's case⁴⁶ hemorrhages around the tracheal glands, amounting in all to less than 3 ounces, caused death with symptoms of internal hemorrhage.

In Rautenberg's⁴⁷ case the bloody stools were found to come from perforation of a gland into the vena cava and esophagus.

It is not alone the pressure of the enlarged glands that causes symptoms of compression in certain organs, for the latter may proceed from the contraction of the gland or the cavity left by it after an acute inflammation. Traction diverticula in the esophagus may arise in this manner. The radiating scars found occasionally in the esophageal wall commonly originate from these processes. We are told by Eichhorst⁴⁸ that contractions in caliber in the trachea or bronchi may originate in similar manner, leaving a puckered, radiating, pigmented scar. In a case reported by Eichhorst and Seydel⁴⁹ the patient died with increasing dyspnea, and many such scars were found in the smaller bronchi, where minute glands had ruptured and eventually caused contraction.

Voelcker⁵⁰ describes a case of surgical emphysema extending from the eyes to the navel in a child in whom an ulcerating bronchial gland opened into the air-passages. With the occurrence of this symptom there was profuse expectoration of blood and pus, with the disappearance of severe dyspnea. This author states that offensive breath in a child is often from an ulcerating bronchial gland. This suspicion would be corroborated by the finding of dulness and especially by hemoptysis.

Extensive mediastinal abscesses may arise from perforation of an ulcerating gland, and may open spontaneously through the chest wall⁵¹ or be evacuated surgically. Class⁵² saw the chest wall perforated spontaneously. Fuller saw death from pyemia from rupture of a suppurating gland into the posterior mediastinum.

Many curious instances of perforation of several organs are on record, as Letulle's, in which the esophagus and pleura were opened by a suppurating gland, and food was found in the purulent pleural contents.⁵³

Numerous cases of recovery after vomiting of pus have been recorded, several being quoted by Hare. I believe the latter author hardly gives due weight to the glandular diseases we are studying as factors in the origination of mediastinal abscess.

The greatest discrepancy exists among different writers and teachers as to the possibility of detecting enlarged bronchial glands clinically. Some would lead one to infer that they may be found as easily as the cardiac dulness, while Ashby and Wright and others doubt if tuberculous glands can be detected, but think that sarcomatous ones may be. Henoeh, than whom no greater authority could be quoted, doubts the possibility of the

diagnosis. Many such contradictory opinions might be brought forward. The truth seems to me to be beyond question that large glands may be detected, for many observers have made the diagnosis and confirmed it; it is likely, however, that not one case in a score reaches the degree of enlargement at which diagnosis is possible.

Guéneau de Mussy³⁹ states that percussion of the spine to the fourth dorsal vertebra, where the trachea ends, gives rise to a tubular resonance, but, if the bronchial glands are enlarged, to dulness. Below the fifth dorsal vertebra he states that vesicular resonance is normal. I certainly do not believe it possible for one examiner in a score to detect these changes in resonance, and, considering the thickness of the solid tissues, and the smallness of the trachea in the child, in whom so much of this work must be done, I think that *a priori* we have no good reason for expecting to obtain any good results here. I have certainly not obtained any.

There seems to be a fair consensus of opinion in favor of the proposition that dulness may be found in the interscapular region when considerable enlargement of the glands exists, although Henoeh and Ashby and Wright⁶³ deny it as mentioned above.

Quain⁴¹ found dulness in one or both sides near the fourth and fifth dorsal vertebrae, 47 times in 58 cases, and under the manubrium sterni in 8 cases. The latter result was obtained by examining after deep expiration with the head held backward.

F. C. Wilson⁶¹ claims that dulness is normal opposite the root of the lungs, at the second and third dorsal vertebrae, which dulness is increased according to the amount of disease in the glands. Guéneau de Mussy³⁹ states that the dulness is found about the last cervical and first three dorsal vertebrae. Hoffmann rather doubts the diagnosis by percussion, front or back, but states that Arnoux⁶² finds dulness from the second to the sixth dorsal vertebrae. He mentions that by palpatory percussion one may feel the increased resistance. This may easily be the case if the glands are large enough to give rise to considerable dulness. As a matter of fact, much more depends upon the size of the mass of diseased glands than upon all other factors, in their detection by percussion.

In front they are more easily found. Authorities are in much better consonance here. The manubrium sterni and the adjoining clavicular articulations, particularly upon the right,⁶² cover the usual dull area. Still, in young children the normal dulness of the thymus gland, and the fact that the lungs cover any but the largest lymph glands, must be taken into account. Further, the difference between the normal apical resonance of the two lungs, and the difficulty of determining slight degrees of dulness in the upper sternal region, must prevent any but fairly marked dulness from being determined.

The cracked-pot sound in the upper chest of children has lost its former significance in the diagnosis of diseases of the bronchial glands, Eustace Smith stating that, on account of the pliancy of the chest-wall in the child, the sound is not necessarily indicative of disease.³⁴

Much divergence is found in the statements as to auscultatory sounds. Voelker¹⁴ believes that alterations in the breath-sounds are more important than those of percussion, especially if they be unilateral. F. C. Wilson⁶¹ finds coarse moist rales with increased vocal resonance and fremitus, in most cases, and bronchial respiration heard further out from the root of the lung the more the glands are diseased. Rilliet and Barthéz³⁶

mention that the solid mass of glands conduct the tubular sound to the surface, even though the lungs be not infiltrated nor broken down. Ashby and Wright⁶³ state that auscultation is still more worthless than percussion unless the glands are very large. These writers speak of the value of weakened respiratory sounds upon one side, though this sign is often masked by tuberculous disease of the lung. Marfan¹ mentions the presence of tubular respiration upon the side of the enlarged glands when they surround a bronchus, heard between the spine and the angle of the scapula. It was present in 14 of Quain's cases.

This writer speaks of an "interseapulo-vertebral souffle" simulating cavernous or amphoric respiration, and lays much stress upon it. Hoffmann speaks of the exaggerated respiration between the scapula, with whistling rales, often with striking difference between the two sides. Widerhofer emphasizes the importance of any great increase in the normal difference between the two sides. Williams⁶⁴ mentions that tubular respiration above the scapula in children is often due to enlarged glands and disappears frequently under treatment.

Quain found diminished respiratory murmur in 14 of his cases, sometimes over a whole lung and sometimes less extensive. Of corneage and tirage we have already spoken sufficiently.

Eustace Smith⁶⁵ has stated that swollen bronchial glands may be detected by bending the child's head backward, thus tilting the bifurcation of the trachea forward, when the bronchial glands, if enlarged, so compress the left innominate vein against the sternum as to give rise to a venous murmur which disappears as the head is brought forward again. The thymus gland, lying in front of the vein, cannot bring about such a result. The murmur, however, may be heard in the normal posture, and with any tumor of the lower neck. It is not produced by flat chest in the absence of glandular enlargement. If old adhesions prevent movement of the trachea the sign cannot be produced by bending the head backward.

It is evident that no very definite diagnosis can be based upon signs and symptoms so indefinite as those we have recorded. The whole matter is in an evolutionary state, and careful work will in a few years give us much better light upon it.

The cases in which the diagnosis is possible are probably generally overlooked because of our general neglect of the subject rather than from any other cause. As instances of the value of closer study of the glands in obscure cases I shall quote briefly the following:
